Detailed studies of the Osaka basin are presented in Yamada and Horike (2007), Sekiguchi et al. (2007), and Iwaki and Iwata (2008), but the results of these studies likely do not accurately characterize the local site transfer function. Instead, we computed the site transfer functions using software developed by C. Mueller, 1997 (“personal communication”), which is based on Haskell’s shear wave propagation method (Haskell 1953, 1960). In this method, the transfer function is computed using linear propagation of vertically incident SH waves and has, as input, data related to the layered media (number of layers, depth of each layer, corresponding Vs, damping, and density), desired depth of computation of transfer function, computation frequency (df), half space substratum shear wave velocity, and density. Damping (ξ) in the software is introduced via the quality factor (Q), a term used by geophysicists that is related to damping by $\xi = 1/(2Q)$.

In summary, during the Tohoku event, the building was subjected to ground level input

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 3 Vertical sections of the building showing major dimensions and locations of triaxial accelerometers

on the 52nd, 38th, 18th, and ground level (First floor). *X* and *Y* denote principal axes of the building (see Fig. 4) (From Çelebi et al. 2012)

acceleration of 3 % of *g*. But the deformations were large enough (to realize sizeable average drift ratios) that the building lost its functionality for several weeks. Elevator cables were entangled. This case, along with others, deserves further studies as to how tall buildings would respond if the ground input accelerations were 20–30 % of *g* with similar low-frequency content that could be caused by a closer earthquake (e.g., ~100 km or less) [e.g., similar to 1923 Kanto and 1994 Kobe earthquakes]. It is important to note that same elevator cable tangling problems also occurred in several tall buildings in the Shinjuku area of Tokyo, Japan (Hisada et al. 2012a).

Furthermore, the actual drift ratios computed from relative displacements divided by story heights between some of the pairs of two consecutive floors are certainly to be larger than the average drift ratios computed from differential displacements between several floors, due to sparse deployments of instruments, as in this case.

Building B: 55-Story Shinjuku Center Building in Shinjuku, Tokyo

According to EERI Special Earthquake Report (EERI Newsletter 2012), the 54-story Shinjuku Center Building was constructed in 1979.

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 4 (Left) Typical plan view (the figure shows 52nd floor) and (right) orientations (From Çelebi et al. 2012)

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 5 (Left) Transfer functions computed for Profile A (near the OSKH02 strong-motion site; www.kik.bosai.go.jp/, last accessed 09/16/2011) and Profiles B and C below the building. The depth of the softer upper two layers (to about 1,500 m depth) below the building does not significantly change the position of the

peaks in the transfer function, particularly for the fundamental mode of the site. (Right) Spectral ratios of amplitude spectra at 52nd floor, 38th floor, and 18th floor with respect to that at first floor. Note that the third mode in X-direction is identified from the ratios. Different colors (red, black, and blue) are used only to distinguish lines corresponding to different floors in descending order

The report states: “The structure’s height is 223 m, and the first natural period of the structure is 5.2 and 6.2 s in two perpendicular directions. In 2009, the building was retrofitted from the 15th to 39th floor with 288 oil dampers that were configured to exhibit a form of deformation dependency, in addition to velocity dependency. In the March quake, the dampers were calculated to have reduced the maximum accelerations by 30 % and roof displacements by 22 %.”

Figure 7 shows a picture of the building and the oil dampers installed in 2009.

Figure 8 shows recorded acceleration time history at first floor and computed displacements at the roof during the Tohoku earthquake at ~375 km from the epicenter. Without the actual data being available, as shown in Fig. 8, the maximum roof displacement is in the transverse (Y) direction and reported as 54.2 cm (Figure adopted from Moehle, 2012, “personal

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 6 Average drift ratios computed from displacements between 52nd, 38th, and 1st floors. In each

frame, the numbers in denominators are distances (in cm) between the designated floors

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 7 (Left) Picture of Shinjuku Center Building and (right) dampers installed in 2009 (From EERI Newsletter 2012)

communication” and revised Sinozaki (2012), “personal communication”). Hosozawa et al. (2012) as well as Takewaki et al. (2011) also confirm these displacements. Assuming that this is the same as the maximum relative displacement between ground floor and the roof, with a height of 216 m (Sinozaki, personal communication), the average drift ratio can be assumed to be $\sim 54/21600 \sim .25\%$ (see Table 2). This is the average. Hence, the maximum drift ratio is $> .25\%$ even with claimed reductions in

maximum accelerations and displacements thanks to the dampers. Without actual data, it is not possible to compute possibly how much larger than 0.25% is the drift ratio between any two consecutive floors.

Again, similar to the discussion related to Building A, the actual drift ratios computed from relative displacements divided by story heights between some of the pairs of two consecutive floors are certainly to be larger than the average drift ratio computed using the maximum

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 8 Recorded first-story accelerations (max $\sim 14\%$ of g) and computed roof displacements

(max ~ 54 cm) during Tohoku earthquake (Figure adopted from J. Moehle and Y. Sinozaki)

roof displacement divided by the height of the building, due to unavailable detailed data, as done in this case.

Buildings C and D: Two Tall Buildings at Kogakuin University Campus, Shinjuku, Tokyo

Without mentioning drift ratios, detailed studies of two buildings on the Kogakuin University Shinjuku, Tokyo, campus are provided by Hisada et al. (2012a, b). Figure 9 shows the vertical sections of the two subject buildings (Fig. 10).

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Table 2 Maximum observed responses (From Hosozawa et al. 2012 and Sinozaki, 2012, “personal communication”)

	Max. Accel. (cm/s/s)		Max displ. (cm)

Roof	236.0	161.3	49.4	54.2
28th floor	112.7	171.3	26.3	33.3
1st floor	94.3	142.1		

Discussion and Conclusions

The four examples presented herein demonstrate that tall buildings at far distances from the epicenter of M9.0 Tohoku earthquake of March 11, 2011 were affected by long-period ground motions. Tall buildings in Tokyo (~ 350 – 375 km from epicenter) and Osaka (~ 770 km from the epicenter) shook for long durations. In addition to these examples, other examples are discussed in Takewaki et al. (2011).

Long-period dominance of ground motions at far distances from the epicenter of the earthquake is confirmed by velocity response spectra of ground motions. These spectra confirm also the recommended design spectra issued 4 months before the Tohoku earthquake by MLIT that accounts for the effects of long periods on tall buildings in 9 regions of Japan that include the buildings discussed herein. Building A is in one of these regions in Osaka and Buildings B, C, and D are all in another region in Shinjuku area of Tokyo.

For small ground-level input ground motions as in the cases presented herein, these four tall buildings deformed significantly to experience sizeable drift ratios as summarized in Table 3. The drift ratios discussed herein are computed from recorded response data from accelerometers that are sparsely deployed in both buildings, hence, the reason for referring them as average drift ratios. Therefore, it is deduced that, for some pairs of consecutive floors, the actual drift ratios are larger than the average. Collection of such data is essential (a) to assess the effect of long-period ground motions on long-period structures caused by sources at large distances and (b) to consider these effects and discuss whether the design processes should consider reducing drift limits to more realistic percentages and lower them to significantly less than 1 % as in Japan for collapse protection level motions (level 2 used for buildings 60 m or taller (The Building Center of Japan 2001a, b)). This ratio is much lower than the 2 % in the United States which is the comparative maximum drift ratio for tall

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 9 Vertical sections showing instrumented floors of 30 storeys Shinjuku Campus Building and 28

storeys STEC Office Building in Shinjuku area of Tokyo, Japan (Figure adopted from Hisada et al. (2012a and b))

buildings for Risk Category 1 or 2 (Table 12.12, ASCE7-10 2007). Even better, drift ratios closer to the 0.2 % imposed by the Chilean Code for Earthquake Resistant Design of Buildings (NCh433.Of96 1996) should be considered. And (c) finally, further applications of unique response modification features are feasible to reduce the drift ratios.

Finally, the following points are made:

1. Behavior and performances of these particular tall buildings far away from the strong shaking source of the M9.0 Tohoku earthquake of 2011 and large-magnitude aftershocks should serve as a reminder that, in the United States as well as in many other countries, risk to such built environments from distant sources must always be considered.
2. The potential risk from closer large-magnitude earthquakes that could subject the buildings to larger peak input motions should be assessed in light of the substantial drift

ratios under the low peak input motions experienced during and following the Tohoku earthquake of 2011.

3. Prolonged cyclic behavior of the buildings, even at moderate to small amplitudes with relatively acceptable elastic drift ratios, can be a cause for low-cycle fatigue. This issue is significant, and unless structural dynamics characteristic of the buildings is modified, low-cycle fatigue can be an important concern for the health of the building in the future.

Summary

One of the most significant effects of the M9.0 Tohoku, Japan, earthquake of March 11, 2011, is the now well-known long-duration (>10 min) shaking of buildings in Japan – particularly those in Tokyo (~350–375 km from the epicenter) and in places as far as Osaka (~770 km from the epicenter). Although none collapsed, the

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 10 Combinations of average drift ratios computed from recorded data of 30 storeys Shinjuku Campus Building and 28 storeys STEC Office Building

strong shaking caused many tall buildings not to be functional for days and weeks.

The purpose of this entry is to discuss the behavior and performance of four tall buildings, considered to be representative of most tall buildings in Tokyo and other locations and from which shaking data were retrieved. Of particular interest is a building in Osaka that almost reached an average of 0.5 % drift ratio – this, with a ground level input motion of ~ 3 % g is significant. What might have happened during an event with input level motions with similar low-frequency content and in 10–20 % g range is a legitimate question that must be pondered. The particular building had serious site effects and was in resonance.

in Shinjuku area of Tokyo, Japan. Highest drift ratio ($\sim 0.5\%$) is computed from displacements in the NS direction between 24th and 22nd floors (bottom left frame)

The other three examples are from Tokyo. For example, based on records obtained from a 54-story building retrofitted with 288 oil dampers on 24 floors, computations show that average drift ratio may have reached ~ 0.3 % and maximum drift ratio likely was $> .3$ %. The maximum allowed by Japanese practice for buildings taller than 60 m and for collapse protection (level 2) motions is 1 % (The Building Center of Japan, 2001a, b).

Performances of tall buildings in many seismically active regions of the world (e.g., Chile, Turkey) or those tall buildings affected by long-distance long-period effects by sources at a distance (e.g., Abu Dhabi, Dubai) are of

interest to the earthquake engineering community. Chile imposes 0.2 % drift limit that results in elastic design. The United States and Turkey impose 2 % drift limit. Such wide variations of drift limits in design practices deserve discussion in light of functionality and performance of tall buildings during the 2011 Tohoku event.

Cone penetration test; Dilatometer test; Shear wave velocity; Small strain shear modulus; Standard penetration test

Introduction

For geotechnical earthquake engineering analysis, soil properties are determined through laboratory and in situ testing. Generally, geotechnical investigations include both components since they provide complementary information. The advantages of in situ testing include testing the soil in its native state, without the disturbance inherent in soil sampling, as well as being more efficient in terms of evaluating a greater volume of soil. While these advantages apply to many soil properties, the effect of disturbance is particularly relevant to dynamic (small strain) soil properties since they are most affected by it. Therefore, correlations have been developed to determine dynamic soil properties from in situ penetration tests including the standard penetration test (SPT), the cone penetration test (CPT), and the Marchetti (Flat Plate) dilatometer test (DMT).

This chapter provides a brief overview of in situ geotechnical penetration tests. Methods of estimating or determining dynamic soil properties from the SPT, CPT, and DMT are explained. A historical overview of correlations, as well as methods for directly measuring the shear wave velocity (V_s), is presented.

The content discussed in this chapter relates to several other entries in the *Encyclopedia of Earthquake Engineering*. While this chapter discusses methods of obtaining dynamic soil properties from penetration tests, closely related entry include ► [Dynamic Soil Properties: In Situ Characterization Using Penetration Tests](#). Because dynamic soil properties are used in seismic analysis and design, the entries covering geotechnical seismic design and analysis may also be of interest. These entries include ► [Seismic Analysis of Masonry Buildings: Numerical Modeling](#), ► [Seismic Design of Dams](#), ► [Seismic Design of Earth-Retaining Structures](#), and ► [Seismic Design of Tunnels](#).

Overview of Penetration Tests

This section describes the SPT, CPT, and DMT equipment and test procedures. Also discussed are the readings taken during each test and the engineering parameters deduced from them.

Standard Penetration Test

The SPT was developed in the 1920s and is the most common in situ penetration test. ASTM D1586 details the test's equipment and procedure. Due to its maturity and popularity, there is vast experience in interpreting SPT results and an extensive database of correlations between the SPT and soil properties. An advantage of the SPT by comparison to other penetration tests is that the SPT is conducted in boreholes where, in addition to the disturbed soil samples obtained by the SPT split-spoon sampler, "undisturbed" soil samples may also be collected. While no sampling method provides a truly undisturbed specimen, some methods and devices such as piston samplers with thin-walled tubes are less disruptive than others. In terms of relating SPT results to dynamic soil properties, this advantage means that in situ SPT results can be compared to laboratory test results from samples collected from the same borehole. There is, however, a caveat: it is virtually impossible to collect undisturbed samples of cohesionless soil without expensive ground freezing and coring. As such, laboratory tests only bracket the soil

properties, while in situ tests reflect the actual combined effects of both material (particles size and shape distribution, mineralogy, etc.) and state (confining stresses, void ratio, etc.) properties.

A drilling rig, shown in Fig. 1, is used to advance boreholes. Depending on soil and groundwater conditions, hollow stem augers (Fig. 2), casing, or bentonite slurry (drilling mud) may be used to maintain borehole stability. The SPT can also be conducted using light-weight portable equipment, such as shown in Fig. 3. Stable, near-surface soils can be tested in shallow boreholes advanced by hand augers or post-hole diggers.

When a test depth is reached, a split-spoon sampler (Fig. 4) is connected to the end of a string of drill rods and lowered into the hole. The split-spoon sampler is cylindrical with a 1.5 in. inner diameter and 2.0 in. outer diameter. Its length is between 1.5 and 2.5 ft. As shown in Fig. 4, the sampler is made of two symmetrical halves, splitting the cylinder lengthwise. This allows for visual inspection and removal of the soil after sampling. Most split-spoon samplers can accommodate a liner, creating a uniform inner diameter. When the liner is not used, the inner diameter is slightly larger, reducing the friction between the incoming soil and sampler. The top of the rod assembly is connected to a drive-weight assembly consisting of a 140 lb hammer, anvil, and a lift-drop system. After lowering the split-spoon sampler to the bottom of the borehole, the drill rod string is attached to the drive-weight assembly.

In the early years of the SPT, equipment and procedural differences made it impossible to compare test results. However, the procedures described in ASTM D1583 and recommendations summarized by Seed et al. (1985) have largely standardized the test, hence its name. The test requires the 140 lb hammer to be raised 30 in. and dropped, driving the sampler into the soil. This process is repeated until the sampler has penetrated 18 in. into the soil at the bottom of the borehole. The number of blows required to advance the sampler each of three 6 in. increments are recorded. After lifting the split-spoon sampler from the borehole and removing the soil

**Dynamic Soil Properties:
In Situ Characterization
Using Penetration Tests,**

Fig. 1 Typical drill rig used to perform the standard penetration test

sample, the borehole is advanced to the next test depth. The SPT is typically performed at 3–5 ft intervals although continuous sampling (1.5 ft test intervals) may also be used.

The SPT blow count (N) is computed by summing the blows from the final two 6 in. increments. The readings from the first 6 in. increment are discarded because a number of factors unrelated to soil properties and state conditions influence the results. These include disturbance of the bottom of the borehole and soil cuttings that have fallen to the bottom of the borehole.

Early SPT hammers transferred approximately 60 % of the theoretical impact energy to the split-spoon sampler. Therefore, many correlations between SPT- N and soil properties are based on this 60 % efficiency. Other factors affecting N include borehole diameter, type of sampler, and rod length. The blow count standardized to 60 % efficiency and corrected for the other factors is designated as N_{60} . Skempton (1986) used Eq. 1 to convert N to N_{60} :

$$N_{60} = \frac{E_m C_B C_S C_R N}{0.60} \quad (1)$$

where:

E_m = hammer efficiency (0.43–0.85; ~0.6 in US).

C_B = correction for borehole diameter (1.0 for 2.5"–4.5" diameter).

C_S = correction for sampler type (1.0 for standard sampler).

C_R = correction for rod length (1.0 for greater than 30' total length).

N = field measured SPT blow count.

Additional information on compensating for hammer efficiency and the correction factors are found in virtually all modern foundation engineering textbooks.

Cone Penetration Test

The CPT was developed in Europe in the 1930s. While many subsequent modifications have been made, the current testing method can be traced to

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 2 Advancing a hollow stem auger through which an SPT will be conducted

Holland. Thus, the test is also referred to as the Dutch cone test. By comparison to the SPT, which provides data only at discrete elevations, the CPT provides continuous soil data with depth. Unlike the SPT, it also exhibits excellent test repeatability.

The CPT device is a probe with a conical tip as shown in Fig. 5. The cone typically has either a 10 cm^2 or 15 cm^2 projected area and a 60° apex angle. A 13.3 cm long friction sleeve is located behind the tip. The disassembled cone, pictured in Fig. 6, shows the tip and friction sleeve separately. The white ring located between the tip and friction sleeve in Fig. 5 is a porous stone which must be saturated prior to the test. A pressure transducer mounted within the probe measures pore water pressure during cone advance and may also be used to monitor excess pore water pressure dissipation when the cone is not advancing in order to estimate soil hydraulic conductivity.

A CPT rig's hydraulic actuator pushes the probe into the ground at a steady speed not exceeding 2 cm/s . The rig's dead weight provides the reaction. As shown in Fig. 7, rigs range in size, and smaller rigs may require anchoring into the ground to provide the needed reaction. The cone is pushed into the ground using continuous hollow rods having the same diameter as a 10 cm^2 cone. To minimize friction along the side of the rods, a larger diameter "friction reducer" may be added between the CPT probe and push rods. Because all readings are taken at the probe and because the friction reducer is located above the probe, it does not affect the test results. If a 15 cm^2 cone is used, the cone itself creates an enlarged hole thus eliminating the need for a friction reducer.

An electronic cable threaded through the hollow rods connects the probe to a data acquisition system at the surface. Readings are taken at small regular depth intervals, typically 2 cm or 5 cm . Three measurements are recorded at each depth: the tip resistance (also called cone bearing), q_c , the side friction (also called local friction), f_{cs} , and the pore water pressure, u . When the test is completed, the probe is withdrawn from the ground, and the hole is filled with grout or bentonite slurry.

Flat Plate Dilatometer Test

The DMT is the newest of the three penetration tests. It was developed in the late 1970s (Marchetti 1980). It is commonly used alongside the CPT since it uses the same rods and pushing system.

The dilatometer blade is shown in Fig. 8. It is 320 mm tall, 95 mm wide, and 14 mm thick. A 60 mm diameter flexible metal diaphragm is located at the center on one side of the blade. The blade is bored to provide access for an electrical line and gas pressure to an area behind the diaphragm. An electrical-pneumatic cable is strung from the blade through the rods and attached to a control unit, shown in Fig. 9.

Unlike the CPT probe which is advanced continuously and paused only for addition of the next rod at 1 m increments, the DMT blade is stopped at predetermined intervals, typically 20 cm , for testing. During advance, the diaphragm is pressed

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 3 Typical light-weight SPT equipment, including a portable tripod SPT system with safety hammer and gas powered auger

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 4 Opened split-spoon sampler revealing clayey soil being tested with a pocket penetrometer

against the blade by lateral earth pressure, an electric circuit is completed, and an audible tone sounds from the dilatometer control unit. When the blade reaches a test depth, its advance is halted, and pressure is added until the diaphragm is unseated from the blade. This breaks a circuit, and the buzzer in the control unit ceases to sound. The gas pressure at which this occurs is recorded

as the “A” reading. When the center of the diaphragm expands to 1.1 mm from the blade, another circuit is completed, and the buzzer begins to sound again. The corresponding pressure is recorded as the “B” reading. Lastly, the diaphragm is slowly deflated until contact with the blade is restored and the buzzer sounds again. This pressure, taken as the “C” reading,

corresponds to pore water pressure in free draining materials as water rapidly fills the gap between the deflating membrane and coarse grained soil. After recording the “C” reading, all pressure is released, and the blade is advanced to the next test depth.

Following data collection, the DMT readings are corrected for the stiffness of the steel diaphragm and gauge offset at atmospheric pressure. With these corrections, the gage readings A, B, and C become corrected pressures p_0 , p_1 , and p_2 ,

respectively. The corrected pressures are used to compute three DMT indices: the lateral stress index, K_D ; the dilatometer modulus, E_D ; and the material index, I_D , as defined by Eqs. 2, 3, and 4:

$$K_D = \frac{p_0 - u_0}{\sigma'_v} \quad (2)$$

$$E_D = 34.7(p_1 - p_0) \quad (3)$$

$$I_D = \frac{p_1 - p_0}{p_0 - u_0} \quad (4)$$

where:

u_0 = hydrostatic water pressure at the test depth.

σ'_v = effective vertical stress at the test depth.

The DMT has a smaller database of results with which to build correlations. However, the test provides a wealth of unique data, affording interesting possibilities for estimating dynamic soil properties through empirical correlations.

Dynamic Soil Properties from SPT

The majority of methods for determining dynamic soil properties from the SPT correlate N to V_s . One can then compute the small strain shear modulus, G_0 by

$$G_0 = \rho V_s^2 \quad (5)$$

where ρ = mass density.

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 5 Electronic cone penetrometer

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 6 Disassembled cone penetrometer

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 7 Types of CPT rigs: (a) trailer mounted, (b) small light-weight CPT rig, (c) large commercial rig, (d) tracked CPT rig

While G_0 is commonly used in dynamic soil analysis, other small strain soil moduli related to G_0 may be of interest. These relationships are given by Eqs. 6 through 8 for the Young's modulus, E ; bulk modulus, B ; and constrained modulus, M , respectively:

$$E = 2G(1 + \nu) \quad (6)$$

$$B = \frac{2G(1 + \nu)}{3(1 - 2\nu)} \quad (7)$$

$$M = \frac{2G(1 - \nu)}{1 - 2\nu} \quad (8)$$

where ν = Poisson's ratio.

Due to their dependence on strain, it is important to remember that all of the soil moduli determined from V_s , which is measured at strains of $\sim 10^{-4}\%$ or

smaller, are small strain moduli. The SPT is a large strain test, and, therefore, correlations between N and V_s should be used with caution. Correlations developed in one geologic setting, and particular soil type should not be expected to accurately predict V_s in other situations.

Many such correlations have been developed, and some are presented in Table 1. The following review summarizes the conditions under which these relationships were developed and is intended to aid the practitioner in choosing an appropriate relationship if no other means of determining V_s exist. As shown in Figs. 10, 11, and 12, for sand, clay, and all soils, respectively, the different V_s versus N correlations do not show very good agreement. The authors therefore recommend using the correlations that were developed under conditions most similar to those of the users' site.

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests, Fig. 8 Flat plate (Marchetti) dilatometer blade

Kanai et al. (1966) used the predominant period of microtremors measured during the Matsushiro earthquake swarm in Nagano, Japan, to estimate V_s of sand deposits. They compared these values to 52 SPTs conducted in the area to develop their correlation. Ohba and Toriuma (1970) developed their relationship from SPT results in alluvial soil deposits in the Osaka area. Fujiwara (1972) reported data collected after the 1968 Tokachi-oki earthquake and base his relationship on that investigation. Ohsaki and Iwasaki (1973) developed their relationship based on approximately 220 sets of data relating N to G_0 from a database collected by the Committee for Evaluation of Structural Safety of High-Rise Buildings, a part of the Japanese Ministry of Construction. Imai (1977) published results of 244 adjacent SPT and down-hole tests across Japan. For the relationship by Ohta and Goto (1978), 300 sets of data from tests conducted in alluvial plains in Japan were sorted by depth, soil type, and age of deposit.

The Japanese Road Association (1980) offered equations for sand and clay, but did not explain the process of developing the relationships. Imai and Tonouchi (1982) used data from 250 sites and 386 SPT boreholes across Japan.

N - V_s in Taipei. Athanasopoulos (1995) developed his correlation based on 221 data pairs from Greek soils. Kayabali (1996) proposed a relationship based on 30 alluvial silty sand deposits from an unspecified location. Pitilakis et al.'s (1999) correlation was developed using 176 pairs of N and V_s data points from the

EURO-SEISTEST database gathered from northern Greece near Thessaloniki.

Wride et al. (2000) proposed a correlation based on results from experiments conducted as part of the Canadian Liquefaction Experiment (CANLEX) at six sand sites in Western Canada. The range of data shown in their equation

Fig. 12 Shear wave velocity versus SPT- N correlations for all soils: (a) correlations developed prior to 1996, (b) more recent correlations

represents the minimum and maximum site-specific values. Jafari et al. (2002) used 57 spectral analyses of surface waves (SASW) tests, 9 down-hole tests, and 26 SPT boreholes to create a correlation for south Tehran. The database used in Andrus et al.'s (2004) correlation came from published work performed in 21 soil layers from eight sites in California, one site in South

Carolina, six sites in Canada, and eight sites in Japan. Hasancebi and Ulusay (2007) correlated 97 pairs of N and V_s measurements from Yenisehir, Turkey. Using V_s measurements from multichannel analysis of surface waves (MASW) testing points adjacent to 38 SPT borehole locations, 162 data pairs were used by Anbazhagan and Sitharam (2008) to develop an N - V_s

relationship for the Bangalore Region. An N - V_s relationship for Delhi was proposed by Hanumantharao and Ramana (2008) based on a subset of SASW-SPT data compiled by the city government from public and private entities.

Uma Maheshwari et al. (2010) used MASW to determine V_s and compared the results to 200 SPTs in order to create their correlation for the Chennai region. Anbazhagan et al. (2013) correlated results from 11 SPTs to MASW results in Lucknow City, India. A correlation for Korean soils was developed by Sun et al. (2013) using cross-hole, down-hole, and up-hole tests from 26 sites. Some references listed in Table 1 were published in languages other than English (Imai and Yoshimura 1970; Shibata 1970; Ohta et al. 1972; Imai et al. 1975; Sisman 1995; Iyisan 1996; Jafari et al. 1997) and are, therefore, not explained in detail.

Other Factors Influencing the SPT Correlations

As shown in Table 1, the majority of the empirical SPT- V_s correlations are in the form of a power fit:

$$V_s = XN^Y \quad (9)$$

This is logical since both V_s and N_{60} depend on confining stress. However, recent research has shown that σ'_v may need to be added explicitly to the empirical N - V_s relationship (Schnaid et al. 2004; Brandenburg et al. 2010). Schnaid et al. (2004) incorporated σ'_v into the following relationships between G_0 and N_{60} :

$$\begin{aligned} G_0 &= 1200(N_{60}\sigma'_{v0}p_a^2)^{1/3} \\ \text{upper bound : cemented sands} \\ G_0 &= 450(N_{60}\sigma'_{v0}p_a^2)^{1/3} \\ \text{lower bound : cemented sands and upper bound :} \\ &\text{uncemented sands} \\ G_0 &= 200(N_{60}\sigma'_{v0}p_a^2)^{1/3} \\ \text{lower bound : uncemented sands} \end{aligned} \quad (10)$$

where p_a = atmospheric pressure.

Additionally, geologic age has been shown to influence the N - V_s relationship (Ohsaki and Iwasaki 1973; Lee 1991). It is often difficult to

accurately determine the geologic age of soil deposits. Therefore, while this factor influences the correlation, it is difficult to apply in practice. When determining which relationship to use in practice, the authors recommend matching the geologic age of the deposit of interest to the geologic age of deposit used to develop the correlation.

In summary, while the SPT is a large strain test, correlations have been developed for over four decades relating corrected and uncorrected blow counts to small strain soil properties, such as V_s and G_0 . Local experience has demonstrated the utility of some of the relationships. However, caution should be used in applying these correlations outside of the conditions for which they were developed.

Dynamic Soil Properties from CPT

The relationships between V_s , G_0 , E_0 , and M_0 were presented in the SPT section of this chapter. The research summarized here compares CPT results to various soil moduli, but other properties of interest can be determined from the relationships above. In the section describing the CPT equipment, procedures, and results, q_c , f_s , and u were introduced. Some relationships described in this section use dimensionless, normalized cone parameters. The normalized cone tip resistance, Q_t ; normalized friction ratio, F_N ; and normalized pore pressure, B_q , were proposed by Robertson (1990) and are given by

$$Q_t = \frac{q_c - \sigma_{v0}}{\sigma'_{v0}} \quad (11)$$

$$F_N = \frac{f_s}{q_t - \sigma_{v0}} * 100\% \quad (12)$$

$$B_q = \frac{\Delta u}{q_t - \sigma_{v0}} \quad (13)$$

where:

σ_{v0} = total stress.

Δu = the difference between measured pore pressure and hydrostatic pore pressure.

Additionally, some of the CPT-based correlations depend on the soil behavior type index, I_c , (Robertson and Wride 1998):

$$I_c = \left[(3.47 - \log Q_t)^2 + (\log F_N + 1.22)^2 \right]^{0.5} \quad (14)$$

Finally, Robertson et al. (1992) introduced an overburden stress-corrected shear wave velocity, V_{s1} :

$$V_{s1} = V_s * \left(\frac{p_a}{\sigma'_{v0}} \right)^{0.25} \quad (15)$$

Just as with the SPT, the following correlations between CPT parameters and small strain dynamic properties are best utilized under the same soil conditions under which they were developed. Relationships between CPT and dynamic soil properties are presented in Table 2.

Baldi et al. (1989) proposed a V_s - G_0 relationship developed with Po River Sand and is meant for uncemented, silica sand. Rix and Stokoe (1992) updated the Baldi et al. (1989) relationship between G_0 and V_s by including laboratory cone penetration tests in calibration chambers:

$$\frac{G_0}{q_c} = 1634 \left(\frac{q_c}{\sigma'_{v0}{}^{0.5}} \right)^{0.75} \quad (16)$$

Hegazy and Mayne (1995) used the general form of equations developed by Mayne and Rix (1993) and replaced initial void ratio, e_0 , and σ'_v and with f_s . This correlation was based on V_s from cross-hole, down-hole, SASW, and the seismic cone penetration tests (SCPT) from 30 sites in the United States, Canada, Norway, and Italy. Mayne and Rix (1995) compiled data from cross-hole, down-hole, SASW, and SCPTs conducted at 31 clay sites in Europe and North America and proposed a V_s - q_c relationship.

Simonini and Cola (2000) reported SCPT results from the Venice Lagoon. After investigating several relationships, the best fit relationship included the B_q pore pressure parameter:

$$G_0 = 21.5 q_c^{0.79} (1 + B_q)^{4.59} \quad (17)$$

Wride et al.'s (2000) relationship was based on tests conducted as part of CANLEX at six sites in Western Canada with loose sand deposits. The denominator in the equation is listed as a range of values because Wride et al. (2000) presented a different value for each of the six sites. The database used in Andrus et al.'s (2004) correlation came from published work from eight sites in California, seven South Carolina, six from Canada, and four from Japan. Schnaid et al. (2004), similar to their N - G_0 relationship, presented a q_c - G_0 relationship based on data from sites in South America, Europe, and the United States:

$$\begin{aligned} G_0 &= 800 (q_c \sigma'_{v0} p_a)^{1/3} \\ &\text{upper bound : cemented sands} \\ G_0 &= 280 (q_c \sigma'_{v0} p_a)^{1/3} \\ &\text{lower bound : cemented sands and upper bound} \\ &\text{: uncemented sands} \\ G_0 &= 110 (q_c \sigma'_{v0} p_a)^{1/3} \\ &\text{lower bound : uncemented sands} \end{aligned} \quad (18)$$

Hegazy and Mayne (2006) added 12 new sites to databases assembled by Mayne and Rix (1993) and Hegazy and Mayne (1995) in order to develop their correlation. Andrus et al. (2007) used 229 data pairs from sites in California, South Carolina, and Japan.

Robertson (2009) utilized a database of more than 100 SCPTs and over 1,000 data pairs in his correlation. Stuedlein's (2010) CPT- V_s correlation is based on 12 SCPTs, yielding 254 data pairs, in the Puyallup River delta near the port of Tacoma, Washington. SCPTs from 17 sites in five areas along the western coast of South Korea were used to develop Sun et al.'s (2013) correlation.

McGann et al. (2014) compared predicted V_s from Andrus et al. (2007), Hegazy and Mayne (2006), and Robertson (2009) to V_s measured using the SCPT following the 2010–2011 Canterbury earthquakes. They found that the relationships over-predicted V_s and recommend future research to develop a Canterbury-specific CPT- V_s relationship. McGann et al. (2014) note that

Using Penetration Tests,
Fig. 13** Degradation of
shear modulus with shear
strain

the relationships particularly over-predict V_s at shallow depths due to a scarcity of shallow depth data in the examined correlations.

Other Factors Influencing the CPT Correlations

While most SPT- V_s correlations were based solely on N , the CPT- V_s correlations sometimes included tip resistance, side friction, pore pressure, and effective stress. However, there are yet other factors which influence the relationship between CPT results and dynamic soil properties. Projects in which these factors were investigated are summarized below.

The age of the deposit plays a significant role on the relationship between CPT results and V_s (Andrus et al. 2007). Indeed, small strain properties, such as V_s , have been shown to increase with time after deposition more rapidly than penetration resistance does (Andrus et al. 2009). Therefore, when applying correlations between CPT and dynamic soil properties, it is important to match the deposit's geologic age to the geologic age of the sites used to develop the correlation.

Cementation is another factor that affects V_s . Similar to the effects of geologic age, V_s is more

sensitive to cementation than penetration resistances are. Schnaid et al.'s (2004) CPT- G_0 correlation (Eq. 18) shows that the upper bound prediction of G_0 in uncemented soils is equal to the lower bound prediction in cemented soils.

It is well known that a soil's V_s is influenced by the average number of particle contacts per grain as these transmit the seismic waves. Since the number of contacts is impossible to determine, void ratio, e_0 , is used as its surrogate. Therefore Mayne and Rix (1993) proposed this relationship for predicting V_s based on CPT results:

$$G_0 = 99.5 p_a^{0.305} q_c^{0.695} e_0^{1.130} \quad (19)$$

The difficulty in applying this relationship in practice is that in situ e_0 is also difficult to predict. Rix and Stokoe (1992), Hegazy and Mayne (1995), and Mayne and Rix (1995) also discuss the importance of e_0 in CPT- V_s correlations.

As shown in Fig. 13, soil modulus degrades with strain. Fahey and Carter (1993) proposed this simple approach to estimating degradation of G :

Dynamic Soil Properties: In Situ Characterization Using Penetration Tests,

Fig. 14 Striking the pad of the CPT rig to generate a shear wave in an SCPT

$$\frac{G}{G_0} = 1 - f \left(\frac{q}{q_{ult}} \right)^g \quad (20)$$

where:

f and g = empirical constants depending on soil type and stress history.

q = applied load causing modulus reduction.

q_{ult} = failure load.

Mayne (2007) suggested that f equals 1 and g is approximately 0.3 ± 0.1 . Mayne (2010) demonstrated the utility of Eq. 20 by using data from laboratory tests and finding good agreement to results from case histories given proper selection of f and g . Combining V_s data from in situ tests with laboratory tests results provides an estimate of G/G_0 . However, there is currently no method for obtaining this relationship entirely from CPT data.

Seismic Cone Penetration Test

The seismic cone penetration test (SCPT) allows for direct measurement of dynamic soil properties rather than through empirical

correlations through the basic CPT readings. An accelerometer placed in the CPT probe is used to record the arrival times of shear waves generated at the ground surface as shown in Fig. 14. A wired sledge hammer completes an electrical circuit when it strikes a support pad of the CPT rig. This triggers the beginning of the data acquisition system's recording and sends the seismic signal into the ground. The arrival of the shear wave at the accelerometer is marked by the onset of a large pulse in the signal trace. The probe is then advanced to the next test depth, and the process is repeated. Common practice is to conduct seismic tests at CPT rod changes (i.e., 1.0 m intervals). However, the authors find that use of 1.0 m intervals does not define soil stratigraphy very well and therefore should not be used for detailed site characterization or liquefaction hazard assessment. However, a 1.0 m interval does provide a reasonable estimate of average dynamic properties and is therefore very reliable for earthquake site response analysis.

An example of SCPT data is presented in Fig. 15. The first step in interpreting the data is

**Dynamic Soil Properties:
In Situ Characterization
Using Penetration Tests,**
Fig. 15 Wave recordings
versus accelerometer depth
in a seismic CPT

to determine the arrival time of the shear wave. Campenella and Stewart (1992) and Brignoli et al. (1996) explain methods of picking shear wave arrival times. The authors use the first intense energy excursion, as described by Brignoli et al. (1996). The determined shear wave arrival times are plotted versus accelerometer depth as shown in Fig. 16. When more than two data points line up, there is reasonable certainty that the elevation increment can be represented by constant V_s . However, this does not necessarily mean that the soil over this increment is the same; it merely shows that the shear wave velocity is constant. By contrast, a break in the V_s profile generally means a change in soil conditions. Figure 16 shows some uncertainty in the layer interface between a depth of 2.8 and

3.3 m. It could also mean that the soil between 2.8 and 3.3 m is different from the soils above and below. This illustrates the need for smaller test intervals if better stratigraphic resolution is desired.

Determining dynamic soil properties directly from measured shear wave velocities such as by the SCPT is obviously more accurate than estimates of V_s based on correlations with CPT resistances. Additionally, research has shown excellent agreement between V_s measured using the SCPT with other methods of measuring V_s , such as down-hole tests, cross-hole tests, SASW, and laboratory measurements (Robertson et al. 1992; Lunne et al. 1997; Schneider et al. 1999, 2001; Mayne 2000; Saftner et al. 2011; etc.).

D

Dynamic Soil Properties from DMT

The first correlations between DMT results and dynamic soil properties used E_D . Baldi et al. (1986) conducted resonant column tests on Ticino sand and compared the results to DMT results from a calibration chamber to develop Eq. 21.

$$\frac{G_0}{E_D} = 2.72 \pm 0.59 \quad (21)$$

Bellotti et al. (1986) used cross-hole testing in Po River sand to determine the correlation presented in Eq. 22.

$$\frac{G_0}{E_D} = 2.2 \pm 0.7 \quad (22)$$

Jamiolkowski et al. (1988) conducted experiments using Ticino sand and found that relative

density, D_r , played a significant role in relating E_D to G_0 , suggesting that previous relationships were too simple.

Hryciw (1990) presented a method of predicting G_0 by the DMT based on results from nine sites in Europe and North America. Hryciw's (1990) relationship included the confining stresses and soil unit weights determined from DMT indices:

$$G_0 = 530 \left(\frac{\sigma'_v}{p_a} \right)^{-0.25} \frac{\frac{\gamma_D}{\gamma_w} - 1}{2.7 - \frac{\gamma_D}{\gamma_w}} K_0^{0.25} (\sigma'_v p_a)^{0.5} \quad (23)$$

where:

γ_D = unit weight as determined by DMT indices.
 γ_w = unit weight of water.

Monaco et al. (2009) collected data from 34 sites in Europe and the United States. The following equations provided estimates of G_0 :

$$\begin{aligned} \text{Clay} \quad \frac{G_0}{M_{DMT}} &= 26.177K_D^{-1.0066} \\ \text{Silt} \quad \frac{G_0}{M_{DMT}} &= 15.686K_D^{-0.921} \\ \text{Sand} \quad \frac{G_0}{M_{DMT}} &= 4.5613K_D^{-0.7967} \end{aligned} \quad (24)$$

where M_{DMT} = constrained dilatometer modulus.

Marchetti (1980) suggested that M_{DMT} can be obtained through the DMT modulus, E_D by

$$M_{DMT} = R_M E_D \quad (25)$$

In turn, R_M is a function of the DMT material index, I_D , and horizontal stress index, K_D :

$$\begin{aligned} \text{if } I_D \leq 0.6 \quad R_M &= 0.14 + 2.36 \log K_D \\ \text{if } I_D \geq 3 \quad R_M &= 0.5 + 2 \log K_D \\ \text{if } 0.3 < I_D < 0.6 \quad R_M &= R_{M0} + (2.5 - R_{M0}) \log K_D \\ &\quad \text{with } R_{M0} = 0.14 + 0.15(I_D - 0.6) \\ \text{if } K_D > 10 \quad R_M &= 0.32 + 2.18 \log K_D \\ \text{if } R_M < 0.85 \quad R_M &= 0.85 \end{aligned} \quad (26)$$

Numerous case histories (i.e., Lacasse 1986; Schmertmann 1986; Schnaid et al. 2000; etc.) have demonstrated that the DMT gives a reliable estimate of M .

Seismic Dilatometer Test

The seismic dilatometer test (SDMT) is similar to the SCPT. The descriptions of equipment, test procedure, and data reduction presented for the SCPT are essentially the same for the SDMT. The advantage of performing SDMT is that one can obtain dynamic soil properties, in this case, V_s , directly, without the uncertainty of correlations. Monaco et al. (2009) emphasized that the availability of SDMT makes direct measurement of V_s the best method for determining dynamic properties from the DMT.

Whereas the SPT and CPT are large strain tests (~10 %), the DMT is a medium strain test (0.05–0.1 %) as shown in Fig. 13. Therefore, there is also an opportunity to develop a method

of determining G/G_0 degradation with strain amplitude (γ) by the DMT. Marchetti et al. (2008) suggest a path for future research, using two points, G (or G_{DMT}) as determined from M_{DMT} and G_0 as determined from V_s to construct the G/G_0 curve. Suggestions for methods of accomplishing this include using I_D to determine soil type and comparing G_{DMT} to G - γ curves recommended for the given soil type, as well as by comparing settlement predictions based on M_{DMT} to predictions from G - γ curves with variable decay rates to determine the best match. Of the three in situ penetration tests discussed in this chapter, the DMT appears to have the most potential for developing G/G_0 - γ relationships from in situ penetration tests.

Summary

Numerous empirical correlations exist between geotechnical in situ penetration test results and dynamic soil properties. These relationships have been developed in various locations around the world and are best applied to sites geologically similar to those at which the correlations were developed. In situ penetration tests that measure V_s directly, such as the SCPT and SDMT, allow determination of small strain dynamic soil properties more accurately than empirical relationships based on the basic SPT-N, CPT- q_c , or DMT indices.

Early Earthquake Warning (EEW) System: Overview

Tsuneo Katayama¹ and Shigeki Horiuchi²

¹Professor emeritus of the University of Tokyo, Bunkyo-ku, Tokyo, Japan

²COE, Home Seismometer Corporation, Shirakawa, Fukushima, Japan

Synonyms

Earthquake alarm system (ElarmS); Earthquake alert system; Earthquake early alarm system; Nakamura's method; Real-time earthquake warning; Urgent earthquake detection and alarm system (UrEDAS)

Introduction

Earthquake early warning (EEW or Real-time earthquake warning) is a system to provide warning of potentially significant shaking in neighboring regions of a strong earthquake within a few seconds upon detection of a severe earthquake. It differs from earthquake prediction which is defined as the specification of the time, location, and magnitude of a future earthquake. EEW is aimed at mitigating earthquake-related damage by allowing countermeasures such as promptly slowing down running trains, controlling

elevators, and enabling people to quickly protect themselves in various environments. Operational EEW systems are currently running in Mexico, Taiwan, and Japan. For well over one decade the Japan Meteorological Agency (JMA) had been developing early warning system to generate immediate alerts after earthquakes, and on October 1, 2007, JMA officially launched EEW service to the residents in Japan through a number of media outlets such as TV and radio. JMA's EEW provides advance announcement of the estimated seismic intensities and expected arrival time of principal motion. The system presently uses about 1,000 seismometers. EEW essentially makes automatic calculation of the (1) focus and (2) magnitude of an earthquake, and estimates, before the arrival of strong motions, (3) the distribution of seismic intensity in the regions where strong tremors are expected. Quickness and robustness are the two key factors. Estimation starts when a few seconds' data from a small number of recording stations are obtained, and the results are updated with time as the number of data increases. The JMA's EEW is divided into two grades: "forecast" and "warning." In the case of the March 11, 2011, off the Pacific coast of Tohoku Earthquake (M_w 9.0), a total of 15 forecasts were issued, and the fourth forecast at 8.6 s after the first trigger became a warning to the general public. When EEW was launched in 2007 in Japan, JMA notified the public the limitations associated with the present EEW,

including (1) Timing, (2) False alarms, (3) Magnitude estimation, and (4) Seismic intensity estimation (JMA 2007). These are all inherent to EEW and difficult to easily solve by the present technology.

There are several ways to define the size of an earthquake. The earthquake magnitude defined by most of the common methods saturates for a large event greater than 8, whereas M_w , or a moment magnitude, is known that such saturation is not observed. In the case of the March 11, 2011, Tsunami earthquake of Japan, JMA released a magnitude as 7.9 soon after the occurrence and updated it to 8.4 during the same day. But the final value released 2 days after the earthquake was M_w 9.0. In this article, M or M_{JMA} , and M_w will be used at different places for different purposes.

Definition

Earthquake early warning (EEW or Real-time earthquake warning) is a system to provide information about potentially significant shaking in neighboring regions of a strong earthquake within a few seconds upon detection of a severe earthquake. EEW differs from earthquake prediction which is defined as the specification of the time, location, and magnitude of a future earthquake. EEW is aimed at mitigating earthquake-related damage by allowing countermeasures such as promptly slowing down running trains, controlling elevators, and enabling people to quickly protect themselves in various environments. When an earthquake occurs, tremors extend out from the seismic focus in a wave-like motion. There are two main types of seismic waves: P -waves with travelling speed of about 7 km/s, and S -waves with travelling speed of about 4 km/s. P -waves are the first to travel outward from the focus and are followed by S -waves, which cause stronger tremors. Most earthquake-induced damage results from S -waves. EEW quickly announces to the public that an earthquake “has” occurred and to inform them of the estimated seismic intensity several (or more) seconds before the arrival of strong tremors.

History

Since 1965, the Japanese National Railway (JNR) has developed and operated an onsite warning system named the Urgent Earthquake Detection and Alarm System (UrEDAS) to control running trains at the time of the occurrence of a large event (Nakamura 1988). Thirty two stations with an average distance of 20 km are used to detect large earthquakes. An alert is issued when the horizontal ground acceleration exceeds 40 cm/s². Although the estimate is rough because the hypocenter is determined by using only the data from one station, the system has nonetheless proven itself effective in estimating the expected ground shaking in the area near each station.

The first prototype of an EEW system in the United States was proposed (Bakun et al. 1994) and developed to rapidly detect the aftershocks of the 1989 Loma Prieta earthquake in California by sending an alert to the crews working in the damaged area. The system worked for 6 months, during which time 19 events with magnitude greater than 3.5 occurred, 12 alerts issued with 2 missed triggers and 1 false alarm.

Operational EEW systems are currently running in Mexico, Taiwan, and Japan. An earthquake alert system in Mexico has been in operation since 1989 that uses 12 stations along the 300 km long Pacific coastline to determine earthquake parameters for large events occurring along the Middle American trench. The main target of the system is Mexico City situated about 300 km south-west of the system (Espinosa-Aranda et al. 1995). Mexican researchers later showed the effectiveness of the warning system. In Taiwan, the Taiwan Central Weather Bureau (CWB) developed an early warning system based on a seismic network consisting of 79 strong motion stations installed across Taiwan and covering an area of 100 ~ 300 km² (Wu and Teng 2002). Since 1995 the network has been used to report event information (location, size, strong motion map) within 1 min after an earthquake occurrence (Teng et al. 1997). To reduce the report time, the concept of a virtual sub-network was

introduced (Wu and Teng 2002). As soon as an event is triggered by at least seven stations, the signals coming from the stations less distant than 60 km from the estimated epicenter are used to characterize the event. The system successfully characterized all the 54 events occurred during a test period of 7 months (December 2000 ~ June 2001), with an average reporting time of 22 s.

For well over one decade the Japan Meteorological Agency (JMA) had been developing early warning system to generate immediate alerts after earthquakes, and on October 1, 2007, JMA officially launched EEW service to the residents in Japan through a number of media outlets such as TV and radio. For the first estimation, JMA introduced an empirical method called B- Δ method (Odaka et al. 2004), which determines epicentral distance from the time changes of *P*-wave amplitudes, measures the direction of hypocenter from the *P*-wave orbital motions and locates hypocenter and magnitude from single station data, though, estimation error is large. During the test period before the official launching (February 2004 ~ July 2006), JMA sent out 855 warnings, only 26 of which were found totally false (Tsukada 2006). JMA's EEW provides advance announcement of the estimated seismic intensities and expected arrival time of principal motion. The system presently uses about 1,000 seismometers, of which about 200 are maintained by JMA and about 800 by the National Research Institute for Earth Science and Disaster Prevention (NIED).

Seismologists in California are currently planning real-time testing of EEW across the state using the ElarmS (Earthquake Alarms Systems) methodology (Allen 2007). The approach uses a network of seismic instruments to detect the first-arriving energy at the surface, the *P*-waves, and translate the information contained in these low amplitude waves into a prediction of the following peak ground shaking.

Development and testing of EEWS is being carried out in several other seismically active regions, for example, Bucharest, Cairo, Istanbul and Naples (Zollo et al. 2009).

Basic Principle of EEW

EEW essentially makes automatic calculation of the (1) focus and (2) magnitude of an earthquake, and estimates, before the arrival of strong motions, (3) the distribution of seismic intensity in the regions where strong tremors are expected. Although there are many standard methodologies available for such purposes, they generally use as many records as possible and are not suited for EEW applications. Quickness and robustness are the two key factors. Without quickness a system cannot satisfy the purpose of mitigating damage, and robustness is critical, because the system should be able to determine the earthquake location with a small number of data often with false triggers, picks from other events, and misidentified picks from energetic, secondary phases.

Figure 1 was taken from a public release material by JMA (2007). Computation starts when a few seconds' data from a small number of recording stations and the results are updated with time as the number of data increases. Previous work on earthquake location for early warning includes several approaches to gain constraints on the location at an earlier time and with fewer observations than for standard earthquake location. A single station approach (or onsite approach) was first proposed by Nakamura (1988) using the correlation between the event magnitude and the characteristic period of *P*-phase defined as the ratio between the energy of the signal and its first derivative. The method is often called the Nakamura's method.

In the standard approaches to EEW, the initial portion of the *P*-wave signal is used to rapidly characterize the earthquake magnitude and to estimate the expected ground shaking at target sites before the arrival of the most damaging waves. Based on the analysis of strong motion records, several empirical scaling relationships between EEW parameters and earthquake size have been derived (Allen and Kanamori 2003) and are implemented or being tested. The original Nakamura method was modified to describe the correlation between the predominant period and the event magnitude for Southern California events. In the ElarmS methodology (Allen 2007),

Early Earthquake Warning (EEW) System: Overview, Fig. 1 Flow of JMA's EEW (JMA 2007)

when the first station triggers, the event is temporarily located beneath that station; after a second station trigger the location moves to a point between the two stations, based on the timing of the arrivals; with three or more triggered arrivals, the event location and origin time is estimated using trilateration and a grid search algorithm.

A group of Japanese seismologists (Horiuchi et al. 2005) successfully developed an earthquake early alarm system that determines earthquake parameters of large events within a few seconds from the arrival of *P*-waves at the closest stations by using the real-time data from the Hi-net and Kanto-Tokai seismic networks that employs about 750 high dynamic range seismic stations covering the whole of the Japan Islands. These networks are maintained by the National Institute for Earth Science and Disaster Prevention (NIED). The alarm system employs a novel method to locate hypocenter using not only the *P*-wave arrival times but also the fact that *P*-waves have not yet arrived at other stations in the network.

The final output of EEW is the shaking intensity at locations where customers live and/or work. In the standard procedures, intensity is

determined from estimated values of hypocenter parameters, magnitude, and empirical attenuation equations. There, however, are difficulties in the quick determination of the magnitude for a large earthquake. Generally speaking, $M8$ -class earthquakes have faults with size of about 100 km. It takes about 30 s until all fault areas are ruptured. Numerical simulation indicates that the movement of faulting continues, for nearly the same duration of time as its fault rupture time, even after the stoppage of the rupture propagation. This means that it takes almost 1 min to observe a complete waveform for an $M8$ -class earthquake making quick determination of the magnitude for large events difficult.

To overcome this difficulty, a parameter has been proposed that quickly and accurately estimates shaking intensity (Yamamoto et al. 2008). The shaking intensity is defined from the amplitude of the filtered acceleration. Usually, displacement defines magnitude from which intensity is estimated. The new principle is based on the assumption that the intensity could be better estimated from the observed acceleration data than from the displacement data. The parameter indicating the earthquake size is named Shaking Intensity Magnitude M_I which is

intended to represent the amplitude of short period seismic waves. Station correction factors are incorporated, because short period waves are greatly amplified in the sedimentary layer just beneath stations. It has been shown that M_I grows much faster to its final value compared with the moment magnitude by conventional methods. Test result for the 2003 Off Miyagi earthquake (M 7.0) indicated that M_I grows to the 95 % of the final size by only 3 s, whereas it required 18 s for M_{JMA} to grow to the final value. Similar results were obtained for several different earthquakes. In the case of 2003 Off Tokachi earthquake of M 8.0, M_I reached about 95 % of its final value at 10 s, and M_{JMA} at about 31 s.

An Example: March 11 Tsunami Earthquake of 2011

The present JMA intensity scale has 10° from intensity 1 that people can barely detect to Intensity 7 the upper limit. Intensity 5 and 6 are divided into two degrees, namely Lower-5, Upper-5, Lower-6, and Upper-6. The JMA's EEW is divided into two grades: "forecast" and "warning." The "forecast" is issued to advanced users when events are estimated to be M 3.5 or larger, or when the expected seismic intensity is 3 or stronger. In the "forecast," the regions are specified where seismic intensity 4 or greater is expected. When estimated intensity becomes Lower-5 or greater at any observation station of the seismic intensity networks covering all over the country, "warning" is issued to the general public in regions where intensity 4 or greater is expected. The "warning" (i.e., forecasts and warnings) is updated as available data increases.

In the case of the March 11, 2011, off the Pacific coast of Tohoku Earthquake (M_w 9.0), which will be hereafter abbreviated as the March 11 Tsunami earthquake caused strong ground motion in the north-eastern part of the Honshu Island. JMA's EEW was first triggered when station OURI detected the initial P -wave at 14:46:40.2, Japan Standard Time, March 11, 2011 (Hoshiba et al. 2011). JMA issued a total of 15 EEW forecasts, but the first forecast issued at 5.4 s after the first trigger considerably underestimated the magnitude as 4.3. The fourth

forecast issued at 8.6 s after the first trigger estimated magnitude to be 7.2 and the expected intensity increased to Lower-5 for central Miyagi prefecture. The fourth forecast, therefore, became a warning to the general public in the Tohoku district, and the warning was automatically broadcast nationwide through TV, radios and cellular phone mails. The EEW arrived the coastal areas where people live at least 15 s earlier than the strong phase of ground motion (intensity Lower-5 or greater on the JMA scale).

Figure 2 shows how the hypocenter and magnitude were updated (Hoshiba et al. 2011). Magnitudes were estimated from maximum displacement amplitude at four stations. Although the JMA's standard procedure uses records from five stations, in the case of March 11 Tsunami earthquake, the instrument at one station was found not properly working and the record from that station was discarded. Color lines represent the different stations, and the black line the median value which was used for EEW. The horizontal axis shows the elapsed time from the first trigger, and offset axis at top the elapsed time from the public warning, i.e., the fourth forecast in this particular case. The solid line indicates the magnitude determined by the P -wave, the broken line that by the S -wave, and the dotted line shows the period during which the magnitude is kept unchanged around the S -wave arrival. White stars show epicenters determined by EEW, one for the first to the seventh forecast (5.4–11.0 s after the first trigger) and another for the next eight (15.9–116.8 s). Focal depth was estimated to be 10 km for all 15 announcements. Red star indicates the epicenter location from the unified JMA catalog (focal depth is 24 km). The resolution of the JMA's EEW is 0.1° for latitude and longitude, and 10 km for focal depth. The fifteenth forecast at 116.8 s after the first trigger estimated the magnitude as 8.1 which is almost the upper limit of JMA displacement magnitude because of amplitude-magnitude saturation.

Figure 3 shows regions where forecasts and public warnings were issued (Hoshiba et al. 2011), and the distribution of estimated seismic intensities at three time points, i.e., at 14:46:48.8 when the "warning" was issued, at

14:47:04.0 when intensity Lower-5 or greater first observed, and at 14:47:46.0 when Tokyo region was first specified as the “forecast” area. Pink areas indicate the region where the “warning” was issued, and the yellow areas are those specified as the target of the “forecast.” The distribution of the observed intensity is shown in Fig. 4. For the Tokyo region, JMA’s EEW estimated intensity 4, and warning was not issued. This was an underestimation, and actual observations reached Upper-5, which corresponds to the level of the warning issuance. After the mainshock, the system did not properly operated for several hours because of high background noise from the coda waves and active aftershocks, and because of power failure and wiring disconnections. For several days, when earthquakes occurred sometimes simultaneously over the wide source region, the system became

confused, and did not always determine the location and magnitude correctly.

In the 19 days from the main shock to March 29, 2011, JMA appropriately issued 15 warnings for the 22 events for which seismic intensity Lower-5 or greater was actually observed. On the other hand, during the same period of time, 45 forecasts were issued, but actual observed intensities did not exceed 2 at any observation station in 11 of the 45 events.

Problems and Prospects

When EEW was launched in 2007 in Japan, JMA notified the public the limitations associated with the present EEW, including (1) Timing, (2) False alarms, (3) Magnitude estimation, and (4) Seismic intensity estimation (JMA 2007). These still are difficult problems to solve in the present technical state.

Early Earthquake Warning (EEW) System: Overview, Fig. 3 Regions of EEW “warning” & “forecast,” and distribution of estimated seismic intensities (Hoshiba et al. 2011)

The window of time from the announcement of an EEW until the arrival of the main tremors is very short, i.e., a matter of seconds (or between several seconds and a few tens of seconds). In areas that are close to the focus of the earthquake, the warning may not be transmitted before strong tremors hit.

Because of limitations imposed by station spacing and the determination and transmission of earthquake source parameters in real-time, JMA system cannot issue an EEW to areas within about 30 km of the earthquake’s hypocenter. It is estimated that about 10 times the number of stations would be needed to issue an effective EEW near focal areas.

JMA’s EEW adopts the single station estimate for the first warning (see Fig. 1), and false EEW’s may be transmitted as a result of noise from accidents, lightning, or device failure. If the

number of stations increases, i.e., if the spacing between stations becomes much smaller than that of today, EEW need not rely upon the single station estimation from the very early stage of warning.

A conventional receiving/alarm unit of an EEW system is equipped with a CPU and memory and is on-line via the Internet. By adding an inexpensive MEMS seismometer and A/D converter, this unit is transformed into a real-time seismic observatory, which may be named a home seismometer (Horiuchi et al. 2008). If the home seismometer is incorporated in the standard receiving unit of EEW, the number of observing stations will dramatically increase. In order to properly cancel the influence of background noise caused by human activity, specially developed software is put in the system. When an event occurs, its predominant

Early Earthquake Warning (EEW) System: Overview, Fig. 4 Distribution of observed intensities during 11, 2011, earthquake (Hoshiba et al. 2011)

frequency, the number of zero crossings, and the time-duration of the triggered event are computed.

There are limits to the accuracy of estimating magnitude, especially for large earthquakes. It is difficult to separate earthquakes and provide accurate warnings when multiple earthquakes occur almost simultaneously or in close proximity to each other. These limitations were actually observed in the case of the March 11 Tsunami earthquake. There are limits to the accuracy of estimating seismic intensity by statistical attenuation formula, as well as limits to the prediction of the effect of the subsurface sedimentary layers beneath stations. Although JMA is continuing to improve the accuracy and timing of its EEW, the above-listed limitations are inherent to EEW and it may take substantial time to make the warning truly practical and accurate.

It is well known that all kinds of magnitude except M_w have the problem of magnitude saturation in magnitude range above about 8.0,

because they are defined by the maximum amplitude of displacement in frequency range higher than several seconds which becomes almost constant against the increase of earthquake size beyond about $M8.0$. Since magnitude by EEW system is defined by the displacement amplitude of P -waves in a few initial seconds, EEW systems also have the problem of magnitude saturation. As shown in Fig. 2, owing to the problem of magnitude saturation, estimated magnitude of the March 11 Tsunami earthquake was 8.1, while M_w is 9.0. While Kanamori proposed that a large earthquake is associated with fault rupture of the order of several tens of seconds, and that fault motion may be estimated from the initial P -wave phase, several seismologists opposed such methodologies are difficult in principle (Kanamori 2005; Rydelek and Horiuchi 2006; Rydelek et al. 2007).

Broadband velocity seismometers are currently well distributed around the globe and might represent an alternative to accelerometric sensors. In other words, a broadband seismometer is an accelerometer equipped with servo-type velocimeter. Velocity is obtained within the instrument itself by single integration of acceleration waveform. And one more integration operation is only needed to retrieve displacement waveform. A limitation to the use of broadband velocity seismometers, however, is that these instruments will saturate at relatively short distances from the source during the occurrence of large earthquakes.

Whether the final magnitude of an earthquake can be predicted while the rupture process is underway remains a controversial issue. For the clarification of this kind of problems, GPS methods may provide an evolutionary measurement of ground motion quantity which is directly related to the permanent ground deformation resulting from coseismic displacement after the ground motion has subsided. Since GPS stations are able to register directly the ground displacement without any risk of saturation without any need of complicated corrections, geodetic displacement time series represent an important complementary contribution to the high-frequency information provided by seismic data (Allen and Ziv 2011; Ohta et al. 2012).

Summary

The ultimate goal of the seismological and earthquake engineering studies is to protect human lives from earthquakes. Earthquake early warning systems (EEW) provide warning to the public that a potentially damaging earthquake “has” occurred before the arrival of strong motions, whereas earthquake prediction is defined as the specification of the time, location, and magnitude of a “future” earthquake. Operational EEW systems are currently running in Mexico, Taiwan, and Japan. When EEW was launched in 2007 in Japan, JMA notified the public the limitations of the present EEW including (1) Timing, (2) False alarms, (3) Magnitude estimation, and (4) Seismic intensity estimation (JMA 2007). These are all inherent to EEW and difficult to easily solve by the present technology.

Earthquake Damage Assessment from VHR Data: Case Studies

Christian Bignami

Introduction

The assessment of damage caused by earthquakes is of primary importance for emergency planning and human rescue, especially in remote areas where infrastructures are weak and communication systems easily break down after natural disasters. In the last decade, the remote sensing instruments, either spaceborne or airborne sensors (i.e., aerial digital cameras), have demonstrated their capabilities to provide valuable tools for damage mapping purposes, especially thanks to the availability of very high-resolution (VHR) images, characterized by pixel size around 1 m or less which are able to capture highly detailed information of the Earth surface.

A wide variety of methodologies can be used to exploit VHR data for building damage assessment, based on visual interpretation approaches, if dealing with optical imagery, and on completely or semiautomated methods as well, especially when Synthetic Aperture Radar is also considered.

The following section focuses on some relevant case studies where VHR images were adopted to map damage caused by destructive earthquakes. The dataset, the adopted methods, and the related achievements are presented for each seismic event.

The January 26, 2001, Gujarat, India, Earthquake

The Gujarat earthquake can be considered the first case study where damage mapping has been

attempted by means of VHR optical images. The region, northwest India, was hit by a very strong seism of 7.7 magnitude, causing destructions in more than 20 districts and killing more than 12,000 people.

This event was studied by using three images acquired by the IKONOS-2 satellite (Saito et al. 2004). One post-event image was taken on the city of Bhuj on February 2, a few days after the earthquake, and no pre-seismic data were available. A second set composed of two images, one before and one after the earthquake, acquired on November 8, 2000, and January 27, 2001, respectively, cover the Ahmedabad city. The used images are 1 m resolution in the panchromatic channel.

A visual analysis of the Bhuj satellite image was performed, aided by the comparison with ground pictures of the damaged buildings. This experiment points out that not all the occurred damage can be easily recognized in a single satellite image. In general, totally collapsed isolated buildings (especially tall buildings) and debris are clearly visible on IKONOS-2 imagery, but other types of damage, such as heavily tilted, partially collapsed buildings or low-story structures, require additional information, e.g., ground photographs, pre-earthquake satellite data, or building heights and footprints (Figs. 1 and 2). Another limitation about the use of optical imagery is, of course, the presence of shadows that prevent the detection of any damage.

The visual interpretation allowed the production of a damage levels map, too. The satellite image was divided in square blocks of one hectare, and the percentage of the collapsed or partially collapsed buildings (which correspond to the grades 4 and 5 of the European Macroseismic Scale 1998, EMS98) within each block is calculated, with respect to the total number of buildings. A damage level classification is then assigned taking into account four levels of damaged buildings percentage: 0–25 % level 1, 25–50 % level 2, 50–75 % level 3, and 75–100 % level 4. A total of 126 blocks were assessed and the final map was obtained in about 4 h by one operator. This satellite extracted map

Earthquake Damage Assessment from VHR Data: Case Studies, Fig. 1 Collapsed single building: ground photo (a) and satellite image (b); the ruins of the building

are visible in the satellite image; *white arrow* in the satellite image shows the look angle of the photo (From Saito et al. 2004)

Earthquake Damage Assessment from VHR Data: Case Studies, Fig. 2 A building with collapsed ground and first floors: ground photo (a) and the same building

circled in white in the satellite image (b); the low-story collapse is not visible in the IKONOS-2 acquisition (From Saito et al. 2004)

was compared with a map derived by a ground survey. Such a comparison highlights that the map obtained from remote sensing data underestimates, on average, the level of damage by one level, and the standard deviation of the difference is 1.58. Despite this discrepancy the overall pattern of the two maps is very similar (Fig. 3).

The higher values of differences (2 and 3 levels) can be ascribed mainly to the resampling of the ground survey map, from its original format (i.e., aggregated at street block scale) to the square block type of satellite map. Indeed, in this step a reclassification of damage level was computed, according to the levels defined in the IKONOS-2 derived assessment.

Earthquake Damage Assessment from VHR Data: Case Studies, Fig. 3 Damage classification levels map obtained from IKONOS-2 post-seismic image (From Saito et al. 2004)

A similar analysis were performed to assess the damage occurred on the west Ahmedabad. As already mentioned, pre- and post-earthquake IKONOS-2 images were available for this case study. The visual interpretation was done considering a grid of 300×300 m. In Ahmedabad less than 60 buildings were totally or partially collapsed; therefore, the inspection was focused on the detection of individual damaged buildings among the intact ones. Twelve locations were marked as damaged buildings, and ten of them were confirmed collapsed by a filed survey.

These first outcomes of VHR images exploitation demonstrated that such type of images can provide useful information to identify the most damaged areas after a destructive earthquake. Even if the level of accuracy is limited by various factors, the information from satellite data, if timely delivered to emergency management stakeholders, can be of great value.

The December 26, 2003, Bam, Iran, Earthquake

On December 26, 2003, at 5:56 local time, a strong earthquake of magnitude 6.6 devastated the city of Bam, in southeast Iran. More than 26,000 people died, 30,000 were injured, and about 85 % of the buildings and infrastructures were destroyed (Hisada et al. 2004).

The city of Bam was observed by the VHR optical sensor of QuickBird satellite before the seismic event on September 30, 2003, and after the earthquake on January 3, 2004. QuickBird can take images at a pixel resolution of 0.6 m in the panchromatic channel and at 2.4 m in the multispectral bands.

To estimate the damage occurred in Bam, the QuickBird data were exploited with different methodologies in a wide number of research papers. Bam is the first case where automated procedures were attempted to extract damage index from VHR optical data.

The visual comparison of the two QuickBird images was adopted to map damage buildings of Bam, following the same methodology and damage classification proposed for the Gujarat earthquake (Saito et al. 2004). A damage classification was also performed at single building scale, by assigning the EMS98 damage grades to each of the detected damaged edifice (Yamazaki et al. 2005). A total of 12,063 buildings were classified (see Fig. 4) after 20 h working for images interpretation.

Besides this extremely time-consuming approach, some automatic methods were tested.

A different approach for damage mapping based on the use of edge information and textural features was also tested (Vu et al. 2005). The edge information is obtained by applying the Prewitt filter (Takagi and Shimoda 1991). In particular, edge intensity (E_i), its variance (E_v), and the ratio of the predominant direction (E_d) of the edge intensity were derived. In addition, the textural parameters *angular second moment* (T_a) and *entropy* (T_e) are derived from edge intensity by calculating the co-occurrence matrix (Baraldi, and Parmiggiani 1995). Pixels within the range of predetermined threshold

Earthquake Damage Assessment from VHR

Data: Case Studies,

Fig. 4 Damage mapping results from pre- and post-seismic data visual comparison. The numbers of identified damaged buildings are 1,597 (grades 1 or 2: blue points), 3,815 (grade 3: green), 1,700 (grade 4: yellow), and 4,951 (grade 5: red) (From Yamazaki et al. 2005)

values of the four parameters E_v , E_d , T_a , and T_c correspond to damaged buildings.

The method was applied to IKONOS-2 and QuickBird post-event data. The vegetated areas were masked out by thresholding the Normalized Difference Vegetation Index (NDVI). The results were compared to the damage map obtained by visual inspection, and it was found that the distribution of detected damage from IKONOS-2 was consistent with these results, while less damage information was detected from the QuickBird image.

In Huyck et al. 2005, a similar method based on textural analysis is performed. On both pre- and post-seismic images from QuickBird, the edge detection is performed, and from the resulting images, the *dissimilarity* textual parameter is calculated. At this stage, the change detection of *dissimilarity* is done. The damage in the post-event data gives a high dissimilarity of edges, while intact buildings yield a low dissimilarity of edges. The image textural difference is then classified, on the base of standard deviation values, and finally, the damage map is extracted by considering the mean value of the class within 200×200 pixel block. The textural analysis was also applied in a multisensor scenario, where the pre-seismic image is the QuickBird acquisition and the post-event one is the IKONOS-2 data, begin the latter resampled at the same resolution of QuickBird image, i.e., from 1 to 0.6 m.

The two damage maps were compared with damage observations obtained from an independent source compiled by US-AID where damage

is categorized by the percentage of collapsed structures: 80–100 %, 50–80 %, 20–50 %, and <20 %. The observed the accuracy rate is high, demonstrating the potential of this damage detection algorithm.

Generally, the use of a pixel by pixel approach with VHR optical data has some limitations because of the presence of some restrictive factors such as different viewing angles of the pre- and post-images (and the related geometric distortions), different sun illumination, and shadows due to the different seasons of the satellite acquisitions. These are the reason why the visual interpretation is considered the most reliable approach, but such problems can be reduced by adopting specific methods. One of the proposed in literature is the object-based technique. This technique analyzes each building (the object in the satellite scene) instead of considering individual pixels. In Gusella et al. 2005, an object-oriented technique was adopted for Bam case study. The object selection is done on the pre-earthquake image, where intact buildings are identified by using, first, a segmentation procedure with a bottom-up region merging strategy and then a supervised classification method by using *eCognition* software. The aim is to separate building objects from nonbuilding objects (e.g., vegetation, cars, and shadows). Then the classified buildings in the pre-event image are superimposed on the post-event one, and to distinguish between collapsed and non-collapsed structures, the post-earthquake buildings are classified, with a supervised approach, for a second time using training set of

Earthquake Damage Assessment from VHR

Data: Case Studies,

Fig. 5 Building damage map for the city of Bam, based on object-oriented analysis of QuickBird imagery captured before and after the event. Collapsed structures are shown in *red* and non-collapsed in *blue* (From Gusella et al. 2005)

Earthquake Damage Assessment from VHR Data: Case Studies, Fig. 6 Building damage map: (a) detail of panchromatic image taken on September 30, 2003; (b) detail of panchromatic image taken on January 3, 2004;

(c) damaged pixels, in *red*, superimposed to the difference between pre- and post-seismic images (From Chini et al. 2009)

damaged and non-damaged objects from the building class. Note that these automated methods require a preliminary co-registration of the two satellite images, to match the geometry of one image on the other (Richards 2006).

The resulting damage map is shown in Fig. 5. The accuracy assessment, performed on a random set of 136 buildings, reaches an overall value of 70.5 %.

A similar way is proposed in the work of Hutchinson and Chen 2005. Here the object selection is performed through a hierarchical segmentation procedure.

The objects selection can also be obtained by following different methods. An alternative solution is the exploitations of the morphological operators (Soille 2003). It is accomplished by applying the closing and the opening filters, with different size, to extract additional features from panchromatic band of VHR pre-seismic

image (Chini et al. 2009). This results in a feature vector which is used as input dataset of an unsupervised classifier. The output of the classifier is therefore the mask of the buildings (i.e., the objects) of Bam city. At this stage, the pixel by pixel normalized difference (ND), i.e., a simple change detection, is computed only on the mask-selected objects, and by setting a threshold on ND value, the damaged buildings are detected. The result of this methodology is presented in Fig. 6. Such approach allowed improving roughly of 15 % the accuracy with respect to the change detection computed over the entire scene.

The January 12, 2010, Port-au-Prince, Haiti, Earthquake

On January 12, 2010, a devastating earthquake of magnitude 7.2 hit the city of Port-au-Prince and

Earthquake Damage Assessment from VHR Data: Case Studies, Fig. 7 (a) Cosmo-SkyMed color composite of Port-au-Prince (R = January 13, G = B = 26 April);

(b) average normalized difference map of Cosmo-SkyMed pair (From Dekker 2011)

E

the surrounding villages in Haiti. In this very destructive event, more than 300,000 people were killed and over one million were displaced. Over 310,000 houses were destroyed or damaged, and medical facilities, educational buildings, and basic infrastructure such as roads, bridges, ports, and airports were severely damaged (Duda and Jones 2011).

As for the case of Bam and Gujarat earthquakes, the VHR optical images were exploited adopting some of the methodologies (or similar) already presented (e.g., Corbane et al. 2011; Tiede et al. 2011; Voigt et al. 2011). For such reason, this section will focus on the methods and results carried out by using VHR images captured from SAR sensors.

During the emergency phase the area of Port-au-Prince was captured by the German SAR sensor of TerraSAR-X mission (Pitz and Miller 2010) and by the Italian constellation COSMO-SkyMed (Covello et al. 2010). Both satellites can acquire VHR images, at X band, reaching resolution of about 1 m on ground, allowing urban area analysis, not only at city block scale but also at single building scale.

SAR data overcome the typical limitations of optical images that cannot provide information in case of cloud coverage, and only daylight satellite passes are suitable for image collection. Actually, SAR instruments, being active sensors, can operate in all weather conditions and day or night orbital

passages, allowing better performances in terms of time latency between satellite tasking and image availability that reflects a prompt response for damage map delivery. It is worth noticing that usually the visual interpretation of VHR SAR images is a very hard task to be done; therefore, most of the approaches rely on automated methods, mainly based on change detection techniques.

For the Haiti case, pre-seismic and post-seismic images from both TerraSAR-X and COSMO-SkyMed satellites were available. The TerraSAR-X images are dated October 13, 2009, and January 20, 2010, while the COSMO-SkyMed pair was acquired on April 26, 2009, and January 15, 2010. The two datasets are on descending orbit, in strip-map mode at 3 m resolution (Dekker 2011).

One of the proposed method relies on a change detection approach which is based on the normalized difference (ND) between the pre- and post-earthquake images. The damage estimation was computed at grid level, by considering the average value of the ND within a grid cell or area. A cell size of 200×200 m was adopted. An alternative damage index proposed for the Haiti case study was estimating the de-correlation coefficient between pre-seismic and post-seismic images (Yonezawa and Takeuchi 2001; Stramondo et al. 2006). It can be obtained by correlating the intensity pixels within a certain grid cells, which was again of 200×200 m for this analysis. In Fig. 7 an example of the damage

index derived from the ND average evaluation obtained from COSMO-SkyMed data and the original SAR image are shown.

The resulting maps were compared with a damage assessment carried out in the framework of the Post Disaster Needs Assessment and Recovery Framework (PDNA) at request of the Government of Haiti (<http://oneresponse.info/Disasters/Haiti/Early%20Recovery/>). The PDNA map was derived from VHR satellite and airborne optical images, on a visual interpretation base. Such map is at building level and on the classification scheme of the EMS98 scale. In order to compare the results, the PDNA map was also averaged with the same grid cells of the SAR-derived maps. The average PDNA damage map shows the same damage distribution pattern as in the average damage maps calculated from TerraSAR-X and Cosmo-SkyMed, with some discrepancies in the eastern area. In addition to this visual comparison, the regression analysis between PDNA map and SAR maps was performed for both ND and grid-cell de-correlation maps. The regression analysis highlighted that, for both satellites, the ND outperforms the de-correlation estimation, but the two indices are not well correlated with the PDNA damage map. Probably not all the damage reflects in a strong enough change of radar backscattering. It can be explained by the different scattering mechanisms and radar orientation (Dekker 2011).

Besides the grid-based approach, a detailed SAR damage assessment was also carried out. This experiment was done on TerraSAR-X data, adopting the logarithmic ratio between the pre- and post-event images as a damage index. The logarithmic ratio is also filtered to remove the well-known speckle effect, and two thresholds for the increase and decrease of radar backscatter are set (6.0 dB and -6.0 dB, respectively). Comparing the resulting map with the PDNA damage assessment, a similar trend in the center of Port-au-Prince was observed, but TerraSAR-X damage map seems weakly correlated at building level, especially in the shanty area of the city. Reason for this latter phenomenon is that shanty areas are less regular and more

compact, and it result in less open double-bounce scattering mechanism.

Summary

This entry describes the main achievements about the very high-resolution (VHR) remote sensing data in the fieldwork of earthquake damage estimation, from their first application. Both optical and SAR imagery exploitation is reported, with the description of the main steps that were adopted to obtain damage detection and assessment maps. Some relevant case studies that can be considered the basis of the VHR remote sensing methodologies are here presented.

Introduction

Disaster management practice around the world evolved gradually, mainly in response to major

events such as earthquakes, volcanic eruptions, floods, or hurricanes. In the last few decades, an ever-increasing vulnerability and complexity of risks brought to prominence integrated and comprehensive, all-hazards approaches, supported by frameworks and structures based upon a shared system of governance and policy making. These approaches presume democratic environment with decentralized and deliberative planning and decision-making processes that integrate risk management into broader sustainable development strategies. The system requires extensive coordination and cooperation among all levels of government, as well as with the many other stakeholders, such as private sector, NGOs, and community groups involved in disaster management. The supporting legislation, policies, guidelines, and plans are commonly based upon sustainable development principles; they also introduce the concept of shared responsibility and empowerment of local communities, reflecting the recognition that it is essential to develop society's overall "adaptive capacity" or resilience (Tierney 2012).

The all-hazards, comprehensive approach to risk and disaster management means that the practice has evolved from its historical sphere of natural hazard events and now incorporates an array of risks, including major environmental and technological, as well as terrorist, events. Furthermore, the approach comprises risk prevention or risk reduction, preparedness or readiness, and response to and recovery from events, internationally recognized as PPRR of risk prevention, preparedness, response, and recovery, or 4Rs of risk reduction, readiness, response, and recovery. These elements are not sequential or mutually exclusive, but each element contains components of the other three and may, at least in part, be simultaneously operational. Each element should be fully integrated through broader planning programs and management processes for disaster management (MCDEM 2005; FEMA 2011).

The subsequent sections of this article focus on one of the elements of the integrated, comprehensive disaster management – disaster recovery framework, with the accent on governance and

leadership as the key elements of successful recovery. The sections provide a discussion on recovery and earthquake recovery, its principles, and its relation to other elements of disaster management (see section "[Recovery: Definition and Principles](#)"); an identification of specific characteristics of governance and leadership in post-earthquake recovery (see section "[Recovery: Governance](#)"); a discussion on governance transformation and leadership in recovery (see section "[Governance Transformation and Leadership in Recovery](#)"); considerations of strengths and weaknesses of different approaches to recovery governance, as well as strategies for successful recovery governance and leadership (see section "[Strengths and Weaknesses of Different Approaches to Earthquake Recovery Governance and Leadership](#)"); and a discussion on recovery governance and social capital and its implications for governance and leadership for resilience and future trends in disaster recovery (see section "[Recovery Governance, Leadership, Social Capital \(or Social Capacities\), and Resilience](#)").

The Role of Governance and Leadership in Disaster Recovery

Recovery: Definition and Principles

Within a broader comprehensive, integrated framework for disaster management, recovery is generally defined as a coordinated process that involves supporting affected communities in reconstruction of the built environment and the restoration of emotional, social, cultural, economic, and natural environment well-being following an emergency. It is recognized that recovery is a complex social and developmental process that involves much more than simply the replacement of what has been destroyed and the rehabilitation of those affected. Effective recovery presents an opportunity to reduce future risks, "build back better," and foster a more resilient community (MCDEM 2005; FEMA 2011; Australian Government 2011; UK Government 2013). Current scholarship recognizes that the actual recovery processes vary with each disaster and that the so-called stages of recovery overlap

with one another, with different groups and sub-regions within disaster-affected areas recovering at different times and in different ways, rendering recovery nonlinear and often iterative (Tierney and Oliver-Smith 2012). Furthermore, recovery is affected not only by local circumstances but by macro-societal and even global factors and, importantly, by their interconnection (*ibid.*). Recovery is not only a set of activities that occur after a disaster but a continuum that involves both pre-disaster and post-disaster planning, as well as risk-reduction and resilience-building activities that link recovery to other aspects of a comprehensive risk management framework (Smith 2011).

It is now widely recognized that recovery is best achieved when the affected communities are actively involved and able to exercise a high degree of self-determination or even take the leadership in developing recovery priorities and activities (MCDEM 2005; FEMA 2011; Australian Government 2011).

Earthquake recovery epitomizes all the above characteristics of recovery. In particular, due to the sudden and devastating nature of earthquakes, especially when they impact urban environments, earthquake recovery presents communities and governments with an enormous and complex long-term process that often challenges preexisting concepts and frameworks.

Historically, scholars postulated that the amount of physical damage from a disaster best correlates with recovery speed, arguing that areas which suffered a higher degree of damage to the built environment and higher injuries and casualties will recover more slowly, requiring more time for reconstruction, with housing in shorter supply (Aldrich 2011). This is particularly relevant for disasters caused by earthquakes. However, there are theories that the scale of damage and loss does not necessarily correlate with recovery rates, and factors such as population density, pace of rebuilding, and socioeconomic status play equally important role (Aldrich 2011). Tierney and Oliver-Smith (2012) define recovery as a socially configured process that is inextricably linked to the recovery of not only the built environment and infrastructure but also

ecosystems, organizations and institutions, economic activity, and culture and, hence, cannot be solely or closely equated with post-disaster reconstruction of the physical environment. It is, rather, a holistic, intricate process requiring complex, integrated, and adaptive governance structures to succeed.

Recovery: Governance

Disaster governance is often defined as a system that enables collaborative activities that bring together multiple organizations (government and nongovernment) to solve problems that extend beyond the purview of any single organization (Tierney 2012). More specifically, Tierney (2012) defines disaster governance as interrelated sets of norms (such as laws and regulations, frameworks, standards), organizational and institutional actors, and practices – across the 4Rs of risk reduction, readiness, response, and recovery – designed to reduce the impacts associated with disasters.

Commonly, governance structures include public sector organizations (federal or national, state or regional, and local governments), nongovernmental organizations (community development corporations, homeowners' associations, special service districts, regional planning organizations, professional associations, and colleges and universities), nonprofit relief organizations (nonprofits, community-based organizations, and foundations), private sector organizations (businesses and corporations, financial and lending institutions, insurance, and media), international relief organizations and nations, and emergent groups and individuals, who together provide three types of resources: financing, policies, and technical assistance (Smith and Birkland 2012). The degree of coordination and integration, underlying values and processes, timing, capacity, and capability of those actors are some of the key factors that determine the effectiveness of recovery processes (Smith and Birkland 2012).

Many countries have developed national frameworks, governance models, and administrative guidelines for recovery management and governance (MCDEM 2005; FEMA 2011;

Earthquake Disaster Recovery: Leadership and Governance, Fig. 1 Multilevel recovery management structure from the New Zealand CDEM group recovery guidelines (MCDEM 2005)

Australian Government 2011; UK Government 2013). In general, all these models reflect the holistic, comprehensive, and integrated risk management approaches based on the principles for sustainable development. They are characterized by decentralized, “bottom-up” structures, with local governments having primary responsibility for supplying disaster-related resources and regional, subnational, national, and international agencies providing support as requested. A similar approach is advocated by the United Nations as well (Fraser-Molekati 2012). For example, New Zealand was one of the first

countries to formalize the approach in its national recovery framework, as illustrated in Fig. 1.

The recovery framework diagram in Fig. 1 depicts the national arrangements in New Zealand, showing the national government as supporting recovery activities lead by the local government in partnership with an array of stakeholders, including private and nongovernment organizations. Depending on the scale of event, the lead agency changes from local to national. The holistic nature of recovery is achieved through integration across different “environments”: social, economic, natural, and built.

Before generalizing recovery arrangements, however, it is important to note that recovery is strongly influenced by global and societal factors that include the economic strength and GDP, the overall ability of societies to address recovery challenges, and the nature and extent of involvement in recovery on the part of international agencies and nongovernment organizations and the outcomes of that involvement, among other factors. If societal systems are weak, this will reflect on recovery arrangements and recovery efforts, and the affected nations will probably be highly dependent on international aid (Tierney and Oliver-Smith 2012).

Researchers found out that, following major disasters, governments are required to undertake complex rebuilding and societal activities in a compressed period of time. This often leads to changes in governance (Olshansky et al. 2012). The same authors summarize recent research findings that identified the effects of time compression on governments and governing in post-disaster recovery as: insufficient capacity to solve problems, provide resources, and take actions; excess demands for information and stakeholder deliberation to make timely decisions; greater needs for organizational integration and coordination; and immediate demands for large amounts of money with existing distribution systems challenged to meet the needs. In the time-compressed recovery environment, bureaucracies often struggle with these and other demands, and as a result, new organizations, both governmental and nongovernmental, emerge to provide more capacity, information, money, and other resources. Sometimes governments create new institutions to manage recovery, as in Louisiana (2005 Hurricane Katrina), Queensland (2010 floods), and Tohoku (2011 earthquake and tsunami). Other times, existing institutions and procedures are modified or adapted, as in Los Angeles (1994 earthquake), Kobe (1995 earthquake), and Chile (2010 earthquake and tsunami) (Johnson and Olshansky 2013). It is important to note that, historically, in times of need, high expectations are placed on governments. Commonly, governments have fronted recovery in all major disasters worldwide, demonstrating different degrees of leadership and effectiveness.

Governance Transformation and Leadership in Recovery

In recent years Australia and New Zealand have experienced large natural disasters. The State of Victoria had bushfires burning for over a month in early 2009, culminating in “Black Saturday” on February 7 and devastating rural communities. For 3 months through the summer of 2010–2011, heavy rains brought extensive flooding to Queensland, compounded by damage from Cyclone Yasi in February 2011. An earthquake sequence devastated central Christchurch in New Zealand, with thousands of quakes occurring over a period of 2 years, between 2010 and 2012. On September 4, 2010, an earthquake with a magnitude of 7.1 occurred only 40 km from the Christchurch City center. The earthquake did not directly cause life loss, but damage to infrastructure and buildings was substantial. It was followed by thousands of aftershocks, some strong enough to cause further damage to the city. On February 22, 2011, a magnitude 6.3 earthquake struck only 6 km from the Christchurch CBD and less than 5 km below ground. This earthquake caused far greater damage than the September earthquake, 185 people died, and the government declared a state of national emergency for the first time in New Zealand history. Christchurch City and the surrounding districts had heavy damage to homes, businesses, infrastructure and education, medical, and community facilities. Further aftershocks caused additional damage, ground failures, and building and infrastructure damage. In all, more than 4,400 aftershocks (of magnitudes greater than three) have been registered from September 2010 to September 2012 (GeoNet 2013).

Both Australia and New Zealand are developed economies with similar political and legal institutions and both had developed recovery frameworks, including governance arrangements, prior to the latest emergency events. However, following these emergencies, the governments in both countries felt compelled to introduce a number of changes to preexisting recovery arrangements, including changes to legislation and governance structures.

Establishment of the special recovery authority in Victoria – Victorian Bushfire Reconstruction and Recovery Authority (VBRRA) – followed Black Saturday, within the preexisting legislative framework (Smart 2012). In the case of the Queensland floods and the Canterbury earthquakes, however, it was perceived that the magnitude and duration of events exhausted the capacity of preexisting institutions to cope, and recovery authorities with greater powers were deemed necessary. In Queensland the Queensland Reconstruction Authority (QldRA) was established (Smart 2012). The QldRA built on the experience by VBRRA, taking onboard recommendations to align with the highest level of government, acquire statutory powers to expedite decision-making and have clearly defined terms of reference (Smith and Birkland 2012). Both Queensland and New Zealand circumvented existing regulations, New Zealand effectively emulating the Queensland experience into its arrangements for the Canterbury Earthquake Recovery Authority (CERA). Both agencies were given similar powers; both could undertake works, enter and acquire land, decide the priorities for reconstruction, and override local government plans and policies; and both had legislated sunset clauses (Smart 2012). The key differences were in their status – CERA was a government department reporting directly to the newly appointed Recovery Minister, while the QldRA was created as a statutory body with a governing board. Effectively, the New Zealand arrangement allowed the government to exert a more direct influence over the recovery process (Smart 2012).

Similar to the governance changes in Australasia, the Great East Japan earthquake of March 11, 2011, triggered a number of major initiatives to transform the current system of disaster mitigation governance in Japan. New government organizations were established: the Reconstruction Agency to deal with recovery and reconstruction (in February 2012) and the Nuclear Regulatory Authority to deal with nuclear safety (September 2012). The role of the Reconstruction Agency is to integrate across different sectors of the national government, as well as to

coordinate between the central and local government (Suzuki and Kaneko 2013).

Following the devastation caused by Hurricane Sandy in October 2012, on January 29, 2013, President Obama signed into law the Sandy Recovery Improvement Act 2013. The legislation introduces significant changes to the way the Federal Emergency Management Agency (FEMA) delivers disaster assistance and empowers FEMA to develop processes and procedures for newly established authorities and their implementation. Prior to the introduction of the act, in December 2012, President Obama issued an executive order that established the Hurricane Sandy Rebuilding Task Force, atypically chaired by the Secretary of Housing and Urban Development, thus allocating the lead role to the Department of Housing and Urban Development, the first for this agency (White House 2012).

It is important not to underestimate the influence Hurricane Katrina had on disaster management in the USA and internationally. The perceived poor recovery following Hurricane Katrina was investigated by the House Select Committee who identified failures at all levels of government to support otherwise exemplary efforts by nongovernment organizations, groups, and individuals. The most important failure for the government was lack of leadership, expressed as lack of imagination, lack of initiative, and lack of adaptive capacity (Waughn and Streib 2006).

The examples from the USA, Australia, New Zealand, and Japan all reflect an acute awareness of the political and fiscal risks and the recognition on the part of respective governments that there is an expectation on governments to demonstrate leadership and deliver on recovery needs. The changes, or transformation of governance that occurred following major disasters, testify to governments taking a leadership role. The newly introduced arrangements were designed to build and sustain institutional capacity for recovery by engaging across a broad sector of government and nongovernment organizations, to allow for formation and growth of partnerships through enabling processes, and to facilitate fueling of the recovery process with money and

information through coordination between different levels and stakeholders.

A closer look at the transformation of governance and arrangements for recovery from Canterbury, New Zealand, earthquakes and the role of the Canterbury Earthquake Recovery Authority (CERA) provides further insights into both requirements for and potential issues with recovery governance and leadership.

Strengths and Weaknesses of Different Approaches to Earthquake Recovery Governance and Leadership

Scholarship has identified that supportive governance is necessary to ensure coping capacities in societies. Governance determines the ways in which a variety of actors at all levels engage and coordinate their efforts in recovery. For engagement and coordination to lead to effective recovery, governance has to ensure broad participation, transparency, accountability, efficiency, and responsiveness (Chen et al. 2013).

Two days after the September 4, 2010, earthquake in Canterbury, Prime Minister John Key announced the appointment to the new Cabinet position of the Minister for Canterbury Earthquake Recovery (CER Minister) and a newly appointed ad hoc Cabinet Committee on Canterbury Earthquake Recovery. Following this, on September 14, 2010, the Canterbury Earthquake Response and Recovery Bill was passed by the Parliament, with urgency and unanimously, and became an Act (CERR Act 2010). The Bill was exempt from the normal parliamentary examination procedures that precede the introduction of new legislation. Its purpose was to facilitate better coordination between impacted local authorities and the central government. The Act also established the Canterbury Earthquake Recovery Commission, comprised of the mayors of the three impacted local authorities and four government appointees (NZ Parliament 2010). Following the devastating earthquake on February 22, 2011, the ad hoc Cabinet Committee on Canterbury Earthquake Recovery began considering new national governance arrangements to manage the recovery effort. The rationale for the proposed change was given as experience from

historical and, especially, more recent events, such as the Victoria bushfires in 2009, Queensland floods in 2011, and Hurricane Katrina in 2005. The Committee recommended that a new, central government public service department be created to ensure leadership and coordination and to balance the central government's contribution to funding while carefully managing its fiscal situation. It was also recommended that normal parliamentary procedures and the normal timeline for establishing a new national department be waived given the emergency situation, allowing for the Canterbury Earthquake Recovery Authority (CERA) to be provisionally established the following day (Johnson and Mamula-Seadon 2014). At the same time, the CERR Act 2010 was repealed, including the dissolution of the Canterbury Earthquake Recovery Commission (CERC), and a new legislation was introduced, effectively upholding the authorities granted under the CERR Act, extending the expiration date of those authorities where appropriate and conferring on the Minister for CER and/or CERA a series of powers that would enable the timely and coordinated recovery of greater Christchurch. The Parliament agreed to an abbreviated legislative process and passed the Canterbury Earthquake Recovery (CER) Act 2011 with a near unanimous vote on April 14, 2011 (Johnson and Mamula-Seadon 2014).

One of the first tasks for the newly established CERA was to develop the Canterbury Recovery Strategy (CERA 2012a) that sets up the vision for the region's recovery and identifies key goals for the recovery. The strategy was developed through a consultative process with other government agencies, local government, and local communities. The key goals of the recovery process are community centered and expressed through the five components of recovery, pertaining to the social, cultural, natural, built, and economic environments, as shown in Fig. 2.

To effect delivery of the complex recovery tasks, the New Zealand government has proposed the following governance structure for CERA (Fig. 3).

As can be seen from Fig. 3, CERA, as a central government agency, and CERA's Chief Executive

Earthquake Disaster Recovery: Leadership and Governance, Fig. 2 Key goals for the six components of recovery following Canterbury earthquakes in 2011 (CERA 2012a)

both report directly to the Minister for Canterbury Earthquake Recovery. A four-person Canterbury Earthquake Recovery Review Panel, appointed by the Minister, was tasked with reviewing and recommending Orders of Council, a mechanism allowing the government to make decisions requiring legal force by bypassing the standard legislative procedure. There is also a cross party parliamentary forum (CPPF), comprised of members of the Parliament from the Greater Christchurch area, established to provide the Minister with information and advice about the operation of the CER Act, and a community forum (CF) of at least 20 members to provide information and advice to the Minister that he must consider in carrying out his duties (CERA 2012b).

To a degree, the proposed recovery governance structure in Canterbury reflects recent societal and political changes, such as the emergence of public-private partnerships, outsourcing, and contracting, involving not only governmental institutions but also private sector and civil society entities, as discussed in research literature (Tierney 2012).

It also reflects the intent to deliver on findings of the World Bank that identified good recovery governance demonstrated during Queensland recovery effort as:

- Introduction of specific agencies to deal with recovery
- Commitment to community engagement

Earthquake Disaster Recovery: Leadership and Governance, Fig. 3 The proposed governance structure and roles for CERA (2012b)

- Government agencies working with the local government in recovery planning
- Incorporation of risk mitigation strategies into recovery planning
- Provision of advice to individuals
- Learning and improving preexisting arrangements (World Bank 2011)

When analyzing recovery governance arrangements pre-earthquake and post-earthquake, Johnson and Mamula-Seadon (2014) identify that the governance structures for managing recovery following the Canterbury earthquakes have transformed significantly at both the national and local levels, in comparison to preexisting arrangements. At the national level, recovery governance has transformed from a national service delivery coordination and support role for locally affected areas to one of increasing national-level

decision-making authority and operational responsibility for recovery activities. The findings demonstrate how post-disaster “time compression” can spotlight the strengths and weaknesses of recovery management processes and governance frameworks or cause distortions. The authors conclude that the effectiveness of vertical coordination of multiple levels of government, capacity building at the local and regional level, and public consultation and deliberation of key decisions are some critical areas of concern (Johnson and Mamula-Seadon 2014). The research revealed that over the course of the first 2 years following the February 22, 2011, earthquake, the transformation of governance structures for managing recovery has mainly focused on strengthening national-level centralization. The driving force behind this transformation was the need to make timely and effective decisions, add capacity and capabilities for the

recovery, and ensure accountability for the considerable public expenditure, among others (Johnson and Mamula-Seadon 2014). The research indicates that there are signs that the centralization may have helped to strengthen coordination among national agencies and expedite policy and decision-making; but the effectiveness of coordination among multiple levels of government, capacity building at the local and regional levels, and public engagement and deliberation of key decisions are some areas where the transformations may not have been as effective. At the local level, recovery governance transformed from a locally led and collaborative approach to a supportive role with, in some cases, little to no involvement in recovery decision-making or implementation. The authors conclude that long-term outcomes of the CERA model and the Canterbury recovery governance transformations require better understanding. They also provide some cautionary notes for future disaster recovery policy making and the development of effective and sustainable integrated recovery governance models for large-scale disaster recovery (Johnson and Mamula-Seadon 2014).

Reflecting on governance and governance transformation that often occurs in recovery, it is important to bear in mind that the last decade or so has seen a dramatic change in the way public service is delivered. Kapucu (2012) observes that the most important reform has occurred not only in the range of agencies involved but in the tools and forms of service delivery. Government agencies are not anymore the sole providers of services that traditionally were considered “public.” In the current environment, often nonprofit and for-profit agencies as well as ordinary citizens have become the stakeholders taking on the roles and responsibilities of service provision at all stages of the process (Kapucu 2012). The term governance depicts the complex web of interactions and interdependencies among a multiplicity of actors that deliver specific services to citizens (Kapucu 2012). The term is also synonymous with collaborative governance and collaborative public management, formed to deliver on complex problems and describe network relationships across different sectors and different levels of the government, all brought together for the purpose of delivering

public good. The mode of operation presupposes consensus-oriented and deliberative processes, with shared decision-making directed toward shaping public policy (Kapucu 2012).

Thus, one of the themes when considering governance structures, and particularly so in the recovery context, is the necessity to understand and address the state-civil society relationships.

Recovery Governance, Leadership, Social Capital (or Social Capacities), and Resilience

Different forms of governance including authority, power, influence, degree of decentralization, and accountability affect disaster recovery. It is important to understand, for instance, how policy initiatives with local communities can be influenced by the way local and national governments work together and how larger trends in national policies affect the capacities of communities to engage with their governmental agencies. Defining the forms of governance that take the energy and commitment individuals and communities show during an emergency and sustain it through appropriately aligned government efforts, especially in response and recovery situations, is one of the key challenges of successful recovery (MNRPG 2013). Furthermore, if successful recovery requires informed, coordinated, and sustained leadership throughout all levels of the government and community and phases of the recovery process (FEMA 2011), it is paramount to design governance structures that foster meaningful engagement between the state and civil society (MNRPG 2013).

Understanding social capital and the power of social groups to organize, generate, and deploy individuals within a community to take decisive action when facing hardships is one of the critical points in recovery governance. Leadership at all levels, including spontaneous, emergent leadership typical of disasters, requires governments to be able to anticipate and adapt. In nearly every national experience, policy leaders have encountered situations in which community members have spontaneously organized and begun to respond and recover to a disaster well before government agencies and programs have mobilized (MNRPG 2013). It is important to understand how various forms of governance align with these

mobilizations that occur largely outside the control and direction of particular agencies. To the extent that community leaders are the potential allies and partners for government authorities, governments need to learn to identify and work with them – and even help create effective leaders (MNRPG 2013).

State-civil society interactions are complex and take many forms – some nations have strong civil society sectors, while in other nations civil society institutions are nascent, weak, or unable to function openly (Tierney and Oliver-Smith 2012). Recent scholarship clearly links the effectiveness of the recovery process to levels of trust and social capital, including social networks or ties, the degree of political prowess and organization, and the degree to which social networks are embedded into recovery processes (Aldrich 2011). There are many examples of successful state-civil society partnership in earthquake recovery, in Haiti, Taiwan, and China, to mention a few (Tierney and Oliver-Smith 2012; Chen et al. 2013).

When, following the earthquake on February 22, 2011, the citizens of Christchurch were asked to identify what makes them resilient, they singled out the ability to take action and engage with others in determining their future as one of the key ingredients for resilience and successful recovery. They felt that the emergent, spontaneous community leaders were the catalyst for the process. When asked to summarize what transformed community members into community leaders and made them so readily accepted by other members of the community, the participants responded that these leaders were found to have local knowledge and connections and have the ability to listen to the community and had a good grasp of community dynamics and needs; they acted on their own initiative and had little need for formal structure in order to be effective; those leaders were described as able to function with little resource, to be flexible, and able to adapt quickly. They were skilled, open minded, selfless, and focused on the well-being of the community. Whereas those leaders were recognized (and subsequently awarded) by the community, the governance mechanisms that had flexibility and adaptability needed to actively

engage community initiatives in the early stages of recovery were seen as lacking (Mamula-Seadon et al. 2012).

Following on the discussion of social capacities (capital), it can be argued that the strength of local relationships is expressed as the degree of prevalent, strong, and sustained-over-time involvement of local groups and individuals in the recovery decision-making process and is a measure of horizontal integration within the governance framework (Smith and Birkland 2012). Participants may include local government officials, nongovernment groups, citizen groups, business owners, local financial institutions, the media, and individual community members. The empowering process usually involves deliberative planning and policy-making strategies at the community level. Recovery governance with poor horizontal integration lacks stakeholder involvement (Smith and Birkland 2012). Vertical integration is defined by strong linkages to state and national organizations, including national foundations, corporations, national lending institutions, and insurance companies (Smith and Birkland 2012). Integrating social capital, ensuring meaningful deliberation and engagement with affected communities, achieving effective vertical coordination with multiple levels of government and other stakeholders, and capacity building at the local and regional level are among key factors for effective recovery governance and leadership.

International policy makers identified that, to a large extent, the challenge of building disaster resilience is a matter of democratic governance. It involves partnering with communities, building mutual support within communities and across jurisdictional boundaries, and sustaining involvement. In general, the work of building resilience, both pre- and post-disaster, demands cooperation among citizens and between subnational and national levels of the government and integration of both the public and private sectors and thus closely resembles the collaborative nature of community recovery. Furthermore, research and policy making have been advanced by views of resilience as a construct formed through the interdependencies that evolve from established

societal patterns and not as a replica of institutional, group, or program arrangements (MNRPG 2013). Governance for recovery requires leadership capable of transforming historical hierarchical government models into adaptable, integrated, networked, multi-stakeholder environments with deliberative and collaborative models of state-civil society – in other words effective governance for recovery is synonymous with effective governance for resilience.

Summary

The shift in disaster management practice toward more integrated and comprehensive, all-hazards approaches based on principles of sustainable development has seen an introduction of frameworks and processes with a shared system of governance and policy making. Common and overlapping responsibilities are apportioned among layers of government and other nongovernment entities in democratic governance systems with decentralized and deliberative planning and decision-making processes. National frameworks, governance models, and administrative guidelines on recovery management reflect the holistic, comprehensive, integrated risk management approach based on the principles for sustainable development and decentralized, “bottom-up” structures, with local governments having primary responsibility for supplying disaster-related resources and regional, subnational, and national agencies providing support as requested. Recovery is considered a continuum that involves both pre-disaster and post-disaster activities. Recovery preplanning is as crucial as risk-reduction and resilience-building activities that link recovery to other aspects of the comprehensive risk management framework. To a varying degree recovery governance structures also reflect recent societal and political changes, such as the emergence of public-private partnerships, outsourcing, and contracting, involving not only governmental institutions but also private sector and civil society entities.

Disaster governance is often defined as a system that enables collaborative activities that

bring together multiple organizations, including the public sector, nongovernmental organizations, nonprofit relief organizations, the private sector, and the community. The degree of coordination and integration, underlying values and processes, timing, capacity, and capability of those actors are some of the key factors that determine effectiveness of recovery processes.

The immediate post-disaster environment creates enormous pressures on governments and societies that require complex rebuilding and societal activities to happen in a compressed period of time. Governments are acutely aware of political and fiscal risks and the expectation to demonstrate leadership and deliver on recovery needs. They rally to provide and unify communities around a shared vision for recovery. Faced with insufficient capacity to solve problems, make timely and effective decisions, add capacity and capabilities for the recovery, ensure accountability for the considerable public expenditure, deliver on excess demands for information and stakeholder deliberation, greater needs for organizational integration and coordination, and immediate demands for large amounts of money with existing distribution systems challenged to meet the needs, governments often struggle. As a result, this may lead to significant transformation in governance. The new arrangements are designed to build and sustain institutional capacity for recovery by engaging across a broad sector of government and nongovernment organizations, to allow for formation and growth of partnerships through enabling processes, and to facilitate fueling of the recovery process with money and information through coordination between different levels and stakeholders. Supportive governance embracing of stakeholder engagement is necessary to ensure coping capacities in societies. For engagement and coordination to lead to effective recovery, governance has to ensure broad participation, transparency, accountability, efficiency, and responsiveness.

Understanding social capital and the power of social groups to organize, generate, and deploy individuals within a community to take decisive action when facing hardships is one of the critical points in the future of recovery governance

and leadership. Integrating social capital, ensuring meaningful deliberation and engagement with affected communities, achieving effective vertical coordination with multiple levels of government and other stakeholders, and capacity building at the local and regional level are among the key factors for effective recovery governance and leadership. An adaptable, integrated, networked, multi-stakeholder environment with deliberative and collaborative models of state-civil society governance for recovery is synonymous with effective governance for resilience.

Introduction

Taiwan is located on the plate boundary where Philippine Sea Plate collides with Eurasian Plate with a very high plate convergence rate of 8.0 cm/year (Yu et al. 1999; Fig. 1). Nearly 18,000 seismic events occur around Taiwan and the vicinity every year (Wu et al. 2008).

Some of the destructive earthquakes caused large casualties, such as the 1906, $M_L = 7.1$ Meishan earthquake (1,258 death); the 1935, $M_L = 7.1$ Hsinchu-Taichung earthquake (3,276 death); and the 1999, $M_L = 7.3$ Chi-Chi earthquake (2,455 death). Earthquake is one of the most serious disasters in Taiwan. Therefore, it is important to seek scientific resolutions to alleviate earthquake hazards.

The earthquake early warning (EEW) system (Wenzel and Zschau 2013; “► [Early Earthquake Warning \(EEW\) System: Overview](#)”) is considered as a useful tool for real-time seismic hazard mitigation. An EEW system provides a few seconds to tens of seconds of advanced warning time for the damage shakings. It allows some mitigation reactions to be taken in a short time. For instance, high-speed trains can slow down to resist strong ground shakings, gas pipelines can be turned off automatically, elevators can be moved to nearby floor and open the doors, surgeries in hospitals can be suspended in time, etc. The early warning time may be too short for people to evacuate from buildings. However, through careful planning, training, and drills, an educated general public can still take necessary response in time to avoid loss of lives from large earthquakes. Two types of EEW systems are operated in the world. One is a front-detection EEW system in which seismometers installed in the earthquake source area give early warnings for more distant urban areas. The other is an on-site EEW system which determines the earthquake parameters from the initial portion of the P waves and predicts the more severe ground shakings of the following S wave trains (Kanamori 2005; Wu and Kanamori 2005a).

Motivation for Taiwan to develop the EEW is the painful experience of the 15 November 1986 Hualien, Taiwan, earthquake of M_L 6.8 (or M_W 7.8). Although the epicenter of that earthquake was located near Hualien, the most severe damage occurred in the Taipei metropolitan area. The distance between Hualien and Taipei is about 120 km. The shear waves traveling over this distance should take more than 30 s. Thus, if a seismic monitoring system can reliably determine the

Earthquake Early Warning System in Taiwan,

Fig. 1 Distribution of the real-time strong-motion stations (*squares*) of the Central Weather Bureau (CWB) and sample virtual subnetwork (VSN) with 60-km radius from the earthquake early warning (EEW) system. *Stars* show epicenters of the four major damage earthquakes

E

location and magnitude within 20 s for a large earthquake that could threaten the metropolitan area, then more than 10 s will be available for emergency response. Consequently, the Central Weather Bureau (CWB), Taiwan, started to develop an experimental system to explore the technology of EEW for the highly seismic area of Hualien in 1993 (Wu et al. 1999). After 20 years efforts, the EEW system is becoming one of the important tools for seismic hazard mitigation in Taiwan, and Taiwan is one of the leading countries in developing EEW system. Progress of the EEW systems in Taiwan will be reported in this entry.

The Hualien Experimental EEW System

The Hualien experimental EEW system is a front-detection type prototype, which was implemented in Hualien area to explore the use

of modern technologies for earthquake early warning purposes by the CWB in 1993. This system consisted of 10 three-component force balanced accelerometer stations (distributed in an aperture of about 20 km) which were telemetered digitally via 9600-baud telephone lines to the CWB Hualien Station. At the Hualien Station, the incoming digital signals are processed in real time and the results are telemetered to the CWB Headquarters in Taipei (Fig. 2). A computer in Hualien handles the communication with Taipei via a dedicated telephone line (19.2 k baud). A parallel computer system in Taipei is used for displaying, processing, and analyzing the received data. It also allows operators in Taipei to access, manage, and control the system in Hualien. A commercial company implemented both the hardware and software under the CWB specifications and directions. The goal of this system was to detect, locate,

Earthquake Early Warning System in Taiwan, Fig. 2 A prototype earthquake early warning system in Hualien. This system consists of 10 three-component accelerometers telemetered digitally via 9600-baud

telephone lines to the CWB Hualien Station. At the Hualien Station, the incoming digital signals are processed in real time and the results are telemetered to the CWB Headquarters in Taipei

and transmit the source information to Taipei within 10 s after the occurrence of a strong earthquake in Hualien. This information could then be disseminated in Taipei prior to the arrival of the strong ground shaking (Lee et al. 1996).

During the test period from May 1994 to October 1994, 32 earthquakes with magnitude ranging from 3.1 to 6.5 were detected. The performance of this system has achieved the goal of rapid detection. It could provide information of earthquake around the Hualien region at about 10 s after the earthquake occurrence. It may offer more than 10 s early warning time to Taipei metropolitan area. However, this dense array cannot provide good station coverage. It results in poor earthquake localization and leads to large uncertainties in magnitude determination (Wu et al. 1999). Base on this experience and the real-time strong-motion signals used for felt earthquake monitoring since 1995, the CWB started to develop EEW system using a telemetered seismic network of digital accelerographs distributed over the entire island (Teng et al. 1997; Wu et al. 1997, 1999).

Front-Detection EEW Systems of the CWB

The Taiwan CWB has utilized its real-time strong-motion network since 1995 (Teng et al. 1997; Wu et al. 1997, 1998) as a basis for the development of rapid earthquake information reporting and EEW capabilities. This real-time strong-motion system consists of 110 telemetered stations (Fig. 1) distributed throughout Taiwan, an area of 100×300 km. Each station has three-component force-balanced accelerometers with signals digitized at 50 samples per sec per channel at 16-bit resolution and telemetered to the CWB Headquarters in Taipei. The full recording dynamic range is ± 2 g, and the sensitivity is sufficient to record events with $M > 4.0$ at distance of 100 km or more.

In order to reduce the earthquake reporting time, a virtual subnetwork (VSN; Wu and Teng 2002) approach and an M_{L10} (Wu et al. 1998) method based on the front-detection early warning approach were utilized in the first stage. The experiment in Hualien, Taiwan, has

demonstrated that earthquake reporting time can be significantly reduced by using a smaller network (Wu et al. 1999). This leads to the design and configuration of a VSN approach. The VSN, automatically configured by the monitoring system, is event-dependent and its configuration varies with time. In hypocenter and magnitude determinations, only stations close to the epicenter (less than 60 km) contribute to the crucial information. Within the framework of the real-time strong-motion network, only signals from a subset of stations are chosen to process and form a VSN network surrounding an event. As soon as the system is triggered by an event, the system automatically extracts signals from a subset of stations and configures a VSN with a 60-km radius centered on that event. Figure 1 also gives a number of possible VSN configurations; each normally consists of about a dozen stations. The extracted data stream for this event forms the basic VSN input data for the subsequent EEW work. By working with the VSN, the reporting time could be substantially reduced, which makes it possible to cover the entire Taiwan region with effective earthquake early warning.

Two major requirements for an EEW system are near real-time estimation of the earthquake location and magnitude. The first requirement on rapid location can be achieved readily in a 10-s time window immediately following the first arrival of P waves. On the other hand, the second requirement of rapid determination of the earthquake magnitude would be more difficult because the shear-wave trains may not be recorded completely within this time window. Therefore, a method for quick magnitude determination for large events needs to be developed. The M_{L10} (Wu et al. 1998) is one of the approaches to determine M_L using first 10 s of the signals. Signals collected by the stations within a 60-km radius from an event are grouped and extracted from the VSN input, which will then be processed in parallel through the VSN software in a dedicated computer. A series of experiments have been conducted to determine the optimum recording time for a 60-km radius network. Results show that 10 s is about the optimum timing. As soon as the 10-s waveforms are

presented at the VSN system, they will be immediately processed to give simulated Wood-Anderson seismograms for magnitude determinations as M_{L10} . The earthquake magnitude M_L cannot be determined in the same time frame due to the incomplete recording of shear waves at some stations. However, the magnitude based on the first 10 s of the signals, i.e., M_{L10} , can be found to correlate with M_L as follows:

$$M_L = 1.28 \times M_{L10} - 0.85 \pm 0.13 \quad (1)$$

By applying Eq. 1 to magnitude determination, the VSN system can determine hypocenter and magnitude with tolerable uncertainty in about 20 s after the occurrence of an earthquake and early warning is thus possible in Taiwan.

During the period from 2006 to 2012, a total of 207 earthquakes with magnitude M_L ranging from 4.5 to 6.9 occurred on land or within 50 km from the coastlines of the Taiwan Island (Fig. 3). A total of 196 earthquakes were detected, processed, and reported in real time. Detecting successful rate is about 95 %. Only 5 % offshore and magnitude smaller than 5.0 events could not be detected automatically. If the off-line manual measurements give correct values, the VSN results give average errors of 6.5 ± 7.9 km and 5.3 ± 9.2 km in epicenter and focal depth, respectively. The error of magnitude is 0.3 ± 0.2 units. The reporting time is 18.6 ± 3.7 s (Fig. 3). Large uncertainties in the estimated magnitude using the initial portion of the seismograms are inevitable. Similar results are also presented in many other studies (e.g., Nakamura 1988; Grecksch and Kumpel 1997; Allen and Kanamori 2003; Kanamori 2005; Wu and Kanamori 2005a, 2008; Wu et al. 2007). For larger offshore earthquakes, the VSN method may underestimate the magnitudes due to the limited intervals of the waveform signals used. To avoid this problem, the magnitude M_T obtained from the average period τ_c (Kanamori 2005) and the dominant period $\tau_p^{\max}$ (Allen and Kanamori 2003) of the initial P waves may offer a satisfactory solution (Hsiao et al. 2009). However, the VSN system has achieved a short earthquake reporting time about 20 s. This can offer

Earthquake Early Warning System in Taiwan, Fig. 3 Comparison of the real-time automatic event locations and magnitudes of the EEW system (subnet) and the manual off-line event locations of the CWB catalog. *Right-bottom* figure shows the EEW reporting times versus magnitudes

Earthquake Early Warning System in Taiwan, Fig. 4 Schematic diagram of the new prototype system for earthquake early warning in the CWB

earthquake early warning for metropolitan areas located 70 km from the epicenter and beyond.

In order to provide warning for regions within 70 km from the epicenter, a new prototype EEW system using a P-wave method is developed using a real-time seismographic network currently in operation in the CWB of Taiwan. This system is based on the Earthworm environment which is capable to carry out integrated analysis of real-time broadband, strong-motion, and short-period signals. The Earthworm system distributed by the United States Geological Survey (USGS) is developed as a multifunctional seismic data processing system. Figure 4 shows the configuration of

prototype EEW system. Real-time seismic signals are packaged and transmitted to the headquarters via various IP-based networks, such as Frame Relay, ADSL, GPRS, or satellite telemetry. Different telemetered networks can be arranged as a secure environment for seismic data transmission. A cluster of computers running the Earthworm system is installed at the central station in Taipei. Instead of M_{L10} , the “ P_d magnitude,” M_{Pd} (Wu and Zhao 2006; Hsiao et al. 2011), is adopted as magnitude indicator in the new system in order to shorten reporting time. P_d is defined as the peak amplitude of the initial P-wave displacement (Wu and Kanamori 2005b). Incoming signals are

processed in real time. When a large earthquake occurs, P-wave arrival times and P_d will be estimated for location and magnitude determinations for EEW purpose. In a test of 54 felt earthquakes, this system can report earthquake information in 18.8 ± 4.1 s after the earthquake occurrence with an average difference in epicenter locations of 6.3 ± 5.7 km and an average difference in depths of 7.9 ± 6.6 km from catalogs. The magnitudes approach a 1:1 relationship to the reported magnitudes with a standard deviation of 0.5 (Hsiao et al. 2011).

VSN system is the current system operated by CWB. When the new system performs as well as the VSN system, it will become one of the systems operating together with the VSN. Currently, the new system is capable of offering earthquake warning information in less than 10 s after the occurrence of events inland. Therefore, the new system will become the major EEW system of the CWB in the future.

A Hybrid of Both On-Site and Front-Detection EEW System Using Low Cost Accelerometers

The EEW system of the CWB can provide earthquake information within 20 s following an earthquake occurrence. Although a 20-s reporting time is already very short, the reporting time can still be reduced if the density of seismic stations in the network can be increased. However, to build such a high-density seismic network by traditional force-balance seismometers, the cost is extremely high. In contrast, Micro Electro Mechanical Systems (MEMS) accelerometers introduced in seismic applications (Holland 2003) are ideal and cost-saving devices for recording strong ground motions. The EEW research group at National Taiwan University (NTU) worked with a technology corporation to develop a P-wave alert device, named “Palert,” that uses MEMS accelerometers for on-site and front-detection EEW purposes. The cost of a Palert device is less than 1/10 of the cost for a traditional accelerometer. The Palert device can record real-time, three-component signals, and

the signal resolution is 16 bits with a -2 g to $+2$ g range. The sampling rate is 100 samples per second. Once an earthquake is detected by the trigger algorithm stored in a Palert, a corresponding earthquake watch or warning alarm is sent by the device. The major trigger algorithms include procedures for continuous monitoring peak ground acceleration (PGA) and the peak amplitude of the filtered (high pass at corner 0.075 Hz) vertical displacement of the P wave (e.g., P_d). Palert also has networking capabilities for streaming real-time acceleration signals to the data collection servers and synchronizing clocks by the Network Time Protocol (NTP). Therefore, it is possible to connect Palert devices to build a front-detection EEW system.

Since 2010, NTU began to build up the Palert real-time strong-motion network. A total of 400 stations were deployed and configured in 2013. Figure 5 provides the distribution of the Palert stations. Most of the stations are located in elementary schools where power and Internet connections are available. Figure 6 provides the configuration of the Palert network. At the field site, real-time signals are processed by the Palert devices. Three-component acceleration signals are processed on-site for detecting P-wave arrival and continuously double integrated to displacement signals for calculating P_d . The real-time signals are sent to the central stations every second simultaneously via the Internet. When an earthquake occurs, the Palert automatically detects P-wave arrival, and once P_d or PGA are larger than 0.35 cm or 80 gal, respectively, the Palert device begins its alert with a warning sound on site. Tasks of the central stations include data clustering and processing. For real-time seismic data processing, real-time signals are processed and stored in the Earthworm system. In the Earthworm system, signals are again processed in order to detect the arrival of the P wave (Hsiao et al. 2011; Chen et al. 2012). P-wave information detected by the Earthworm platform is also sent to a shared memory for later fusion process. During the final stage, once eight Palert stations are triggered, an event is declared. The TcPd.c program fetches the event parameters stored within the shared memory and computes

magnitudes given by the real-time *Palert* network and the CWB published earthquake catalogs. (d) The reporting times of the *Palert* network

the earthquake early warning information. The hypocentral location is determined using a traditional earthquake location algorithm with a half-space linear increasing velocity model (Wu and Lin 2013). The magnitude (M_p) determination is based on the relationship of peak displacement and velocity amplitudes of initial three P waves and hypocentral distance (Wu and Zhao 2006; Wu et al. 2013).

During the period from June 2012 to August 2013, a total of 33 earthquakes with M_L magnitudes ranging from 4.6 to 6.3 have been detected. Front-detection EEW performance of the *Palert* system is summarized in Figure 7. Results of the *Palert* network were compared with those reported by the CWB. Hypocenters provided by

the *Palert* network versus those from the CWB catalogue are plotted in Fig. 7. The hypocenters determined by the two systems are generally in agreement. Only a few offshore events have larger differences. The average difference in epicenter location is 14.1 km with a standard deviation of 15.1 km. The average difference in focal depth is 1.6 km with a standard deviation of 18.5 km. The magnitudes determined by the *Palert* network and the corresponding M_L values from the CWB earthquake catalog are listed. Figure 7 also provides a plot of M_p values against those of the CWB earthquake catalog. In general, magnitude uncertainty is in the order of 0.3, which is an acceptable value for EEW application. More than 1 year operation, the *Palert*

Earthquake Early Warning System in Taiwan, Fig. 8 The early warning leading times for *Palert* stations close to the epicentral region of the 2 June 2013 Nantou

M_L 6.3 earthquake. The leading time is defined as the interval between the time of on-site sound alert and the time of PGA

network achieves an early warning reporting time, the time between earthquake occurrence and the time of the system providing earthquake information, from 9 to 28 s, with an average of 15.5 s and a standard deviation of 4.3 s (Fig. 7). The results indicate that for the majority of events the *Palert* EEWs can issue an early warning report within approximately 20 s after an earthquake occurrence. It shows that it is feasible to use *Palert* devices to build a practical front-detection EEW system. The system could offer EEW messages for the regions at distance more than 60 km from the earthquake epicenter.

Front-detection EEW system could not offer early warning messages to the epicentral regions.

On-site approach may possibly offer early warning for regions close to the epicenter. *Palert* has an on-site alert function that triggers a warning sound once P_d exceeds 0.35 cm or PGA is larger than 80 gal (Wu et al. 2011). The major advantage of the on-site P_d approach is that it can provide a valuable early warning for epicentral regions. Figure 8 shows the resulting early warning leading times near the epicentral regions for the 2 June 2013 Nantou M_L 6.3 earthquake. So far, this earthquake is the largest event that has been detected by the *Palert* network. The early warning leading time is defined as the interval between the time when the filtered vertical displacement exceeds 0.35 cm or acceleration large than

80 gal and the time of the PGA. Only one station (W093) has a very short leading time. However, the majority of stations which have PGA larger than 80 gal have a 1–9 s leading time. It is worth noting that those stations which are very close to the epicenter (W07F, W072, W07C, W078, W08E, and W07A) and recorded of PGA larger than 400 gal had leading times from 3 to 6 s. Such times are long enough for automatic systems to make an emergency safety response.

Summary

In this paper, the progress on EEW in Taiwan is introduced in particular for the systems run by CWB and NTU. Both systems are able to reduce the EEW reporting within 20 s. This represents a significant step toward the capability of providing realistic EEW in Taiwan. The CWB is the agency responsible agency for earthquake reporting and NTU is a research and education institute. So, the front-detection EEW message is officially announced by the CWB. However, the technique developed by NTU will be transferred to the CWB for routine operation. Currently, front-detection EEW systems in Taiwan still cannot offer EEW messages for regions within 50 km from an earthquake epicenter. However, an on-site method can provide 3–6 s leading time before the largest shaking based on the results from the NTU EEW system. Thus, it is envisioned that a hybrid approach such as the NTU EEW system will be one of the future systems for real operation.

Introduction

Accurate estimation of an earthquake location is an essential starting point for quantitative seismological analyses, such as seismic hazard analyses and seismotectonics. Although the fundamentals of earthquake location were established nearly a century ago, improvements in robustness to data errors and nonoptimal network configuration have enabled semiautomation of the event location process. Further, algorithmic advancements and improved models of seismic wave speed in the Earth's interior continue to improve event location accuracy.

In the context of this entry, earthquake epicenter will be taken to mean the surface projection of the estimated latitude and longitude where fault rupture initiates. Earthquake location means epicenter and depth, and hypocenter means location and origin time. After a short introduction to the history of the methods for the determination of earthquake locations, a description of modern methods for single-event location is given. The final sections discuss event locations with 3D velocity models and multiple-event location methods.

A Short History of Catalogs/Bulletins

Excellent primary and secondary sources of catalog information about earthquake hypocenters and magnitudes can be found in the archives of the International Seismological Centre (ISC) and the US Geological Survey's National Earthquake Information Center (NEIC). These archives contain earthquake source parameters reported by a number of catalogs, bulletins, and studies of individual earthquakes. The archives are available in computer-readable format that are either directly determined by the ISC and NEIC or derived from published papers and institutional contributions. The most valuable catalog included in these databases for the historical period (before 1964) is the one derived from Gutenberg and Richter's book *Seismicity of the Earth* (1954), which provides hypocenters and magnitudes for most of the larger earthquakes occurring between 1904 and 1952. Other catalogs of large earthquakes are used mainly as sources of magnitude information.

Bulletins differ from catalogs in that they contain reported arrival times for seismic phases that are associated with each event. Seismic phases include first-arriving P-waves, S-waves, and additional seismic phases that are used to estimate a hypocenter. Prior to 1964 the primary sources of historical phase data are the bulletins of the International Seismological Summary (ISS) and the Bureau Central International de Seismologie (BCIS). Unfortunately, until only recently, these bulletins were mainly preserved in printed form and were not in a computer-ready, digital format. For the modern period (1964–present), instrumental phase data for moderate-to-large earthquakes worldwide are readily available in digital format from both the ISC and the NEIC.

In 1997, a project to relocate instrumentally recorded earthquakes during the period 1900–1963 was initiated. In this project the printed ISS bulletins were converted into digital form by scanning the ISS bulletin pages and applying an optical character recognition procedure to produce a digital arrival-time database of events. The initial processing of larger events in this database, combined with recent earthquakes in the ISC bulletin, resulted in a preliminary catalog for the twentieth century, the so-called Centennial Catalog (Engdahl and Villaseñor 2002). Recently, this catalog was substantially revised and expanded for the period 1900–2009 under the Global Earthquake Model (GEM) project (Storchak et al. 2013). The ISC-GEM catalog provides substantially improved earthquake hypocenters and magnitudes, along with their formal uncertainties.

Early Location Methods

John Milne, one of the founding fathers of instrumental seismology, devised some of the first quantitatively based methods for earthquake location, such as the methods of circles and hyperbolas (Milne 1886). The method of circles is similar in concept to the S minus P time location method. Assuming that a velocity model exists to specify the average P and S velocities, the difference between S and

Earthquake Location, Fig. 1 Illustration of the method of circles. If circles are drawn around the recording stations (triangles) with a radius defined by Eqs. 1 or 2, then the intersection of the circles determines the area containing the epicenter

P arrival time provides an estimate of distance from the station to the epicenter d :

$$d = \frac{v_P v_S (\tau_S - \tau_P)}{v_P - v_S} \quad (1)$$

where v is the velocity and τ is the arrival time for the phases indicated with the index. The expression further simplifies with the assumption that the ratio of P and S velocities is typically $\sqrt{3}$. Then Eq. 1 becomes

$$d = \frac{v_P (\tau_S - \tau_P)}{\sqrt{3} - 1} \quad (2)$$

Thus, for typical values of average P velocities, 8–10 times the S – P arrival-time difference gives a reasonable estimate of the epicentral distance from the station. Figure 1 shows that if there are several stations, the intersection of the circles drawn around the stations with the corresponding radius of the epicentral distance will define the most likely position of the epicenter. Note that because the velocity model is never perfect and the arrival times suffer from measurement errors, the circles do not intersect in a point. The area of the intersection is an indication of epicenter uncertainty. One of the major limitations of the method is that it gives little constraint on the source depth. Furthermore, measurement error

for the later-arriving S phase can be large, resulting in a correspondingly large error in the estimate of epicentral distance.

These early graphical methods evolved into a method of earthquake location by triangulation, drawing arcs from station locations with a compass on a large globe using a tape measure calibrated for the travel time. For many years the US Coast and Geodetic Survey (USC&GS) used this method to produce the Preliminary Determination of Epicenters (PDE) bulletin.

The Basic Location Problem

The location estimate is determined by finding the location and origin time (hypocenter) that minimizes the difference between observations and predictions of phase arrival times as measured at a network of seismographic stations. Methods to solve the location problem typically assume that both the phase associations (i.e., all associated phases belong to the event) and the phase identifications (or at least whether a phase is P or S type) are correct. The arrival-time prediction for each observation is the event origin time plus a calculation of travel time between the event and the observing station for the designated phase. Historically, travel time was read from an empirical travel-time table. Modern methods integrate time along ray paths for each phase within a model of wave speed for the Earth's interior. To ease the potentially heavy computational burden of computing ray paths and travel times in a heterogeneous Earth model, most location algorithms use radially symmetric velocity models, for which velocity is only a function of depth. For local velocity models, this translates to a horizontally layered structure.

Computationally efficient methods have been developed to compute travel times in radially symmetric Earth models (Buland and Chapman 1983). To further increase computational speed, precomputed travel times for various phases are often collected in travel-time tables for a set of depth and distance values. These travel-time tables are then used as lookup tables and interpolated to get travel-time predictions for a specific

phase, depth, and distance triplet. The predicted travel times may be adjusted by various corrections, to account for the ellipticity of the Earth and topographical effects, as well as path corrections to account for three-dimensional velocity heterogeneities. Thus, the time residual for a phase at the i th station is defined as

$$d_i = t_i^{obs} - t_i^{pred} = t_i^{obs} - (T^o + t_i^{model} + t_i^{corr}) \quad (3)$$

where d is the time residual; t^{obs} and t^{pred} are the observed and predicted arrival times, respectively; T^o is the origin time; t^{model} is the travel-time table value; and t^{corr} is the sum of applicable travel-time corrections. The predicted travel time for a phase arrival is a function of the station and source coordinates as well as the velocity model. For local earthquake location problems, where the epicentral distances do not exceed a few hundred kilometers, a horizontally layered, or “flat” Earth, model can be used without imparting significant computational error. Representing the Earth as a series of horizontal layers with constant or slowly varying velocities dramatically simplifies the calculation of travel-time predictions as they can be expressed in closed form in a Cartesian coordinate system. In either case, travel time is a nonlinear function of event location, requiring the use of nonlinear inversion methods.

Geiger's Method

One of the earliest numerical methods for earthquake location by the ISS consisted of least-squares estimations using a desk calculator. With the advent of computer processing, the method of Geiger (1910) was used to develop programs for routine earthquake location. Among the first of these programs were those developed by Bolt (1960) for the ISS, by Engdahl and Gunst (1966) for the USC&GS, and by Edouard Arnold for the ISC.

Geiger's insight was that if the initial source coordinates (i.e., the user's initial guess for the starting position for the hypocenter, $[x_0, y_0, z_0, T^o]_0^T$) are sufficiently close to the true

Earthquake Location, Fig. 2 Neighborhood algorithm search results for the $M_w = 6.7$, January 17, 1929, 11:45:44 earthquake in Venezuela. The misfit surface exhibits multiple minima (also note the trade-off between

origin time and depth). The *square* represents the best solution from the neighborhood search; the star shows the final location

hypocenter, the residuals can be expanded in a Taylor series with the higher-order terms considered to be negligible.

$$d_i = \frac{\partial t_i}{\partial x} \Delta x + \frac{\partial t_i}{\partial y} \Delta y + \frac{\partial t_i}{\partial z} \Delta z + \Delta T^o \quad (4)$$

where d is the travel-time residual, z is event depth, y and x are local event coordinates in the direction of latitude and longitude, T^o is event origin time, and t is phase travel time. This yields a linear system of N equations (N = number of arrival-time observations) with $M \leq 4$ model parameters written in matrix form as

$$\mathbf{G}\mathbf{m} = \mathbf{d} \quad (5)$$

where $\mathbf{G}$ is the $(N \times M)$ design matrix containing the partial derivatives for N data with respect to M model parameters, $\mathbf{m}$ is the $(M \times 1)$ model adjustment vector, $[\Delta x, \Delta y, \Delta z, \Delta T^o]^T$, and $\mathbf{d}$ is the $(N \times 1)$ vector of time residuals. Geiger proposed to solve the system of equations with an iterative least-squares method by minimizing the root mean square of residuals. After each

iteration k , the model parameters are adjusted by the current estimate of the adjustment vector, $\mathbf{m}_{k+1} = \mathbf{m}_k + \mathbf{m}_{\text{est}}$, where $\mathbf{m}_{\text{est}}$ is the least-squares solution of Eq. 5. Textbook linear algebra informs us that the solution to Eq. 5 is

$$\mathbf{m}_{\text{est}} = (\mathbf{G}^T \mathbf{G})^{-1} \mathbf{G}^T \mathbf{d} \quad (6)$$

Practically all linearized location algorithms build on Geiger's method. Note that Geiger's linearization does not make the location problem linear; it assumes that the solution to the nonlinear problem can be found by iteratively solving a linear approximation to the problem, which enables application of standard numerical methods.

The assumption that the initial source coordinates are sufficiently close to the true hypocenter makes linearized location algorithms very sensitive to the initial guess for the starting hypocenter. Figure 2 shows the misfit surface (the root mean square of time residuals) obtained with the neighborhood algorithm (Sambridge and Kennett 2001), a nonlinear grid search algorithm (a more

detailed description is given later in the section Nonlinear Methods) for the $M_w = 6.7$, January 17, 1929, event in Venezuela. The station coverage for this event was quite poor as most of the recording stations were in Europe and North America. The misfit surface exhibits multiple minima, and a linearized location algorithm could easily be trapped in any of them, depending on the starting hypocenter. In this case the neighborhood algorithm provided a good starting location (square) for the linearized location algorithm that further refined the initial guess (star). The right panel clearly demonstrates the trade-off between depth and origin time. It should be noted that the problem of multiple local minima in the misfit surface is a particularly serious problem for local event locations in areas with strong 3D velocity heterogeneities.

Velocity Models/Travel-Time Tables

Since knowledge of Earth structure is derived primarily from earthquake data, the earliest Earth models were at best rudimentary, often inaccurate and incomplete. Travel-time predictions determined using early Earth models were valid only for shallow-depth earthquakes. For many years the standard travel-time tables used by the ISC and the NEIC were the Jeffreys and Bullen tables published in 1940. Although the limitations of these tables had been known for some time, until only the 1990s no other tables could provide such a complete representation of travel times for P, S, and other later-arriving phases.

In 1987 the International Association of Seismology and Physics of the Earth's Interior (IASPEI) initiated a major international effort to construct new global travel-time tables for earthquake location and phase identification. A model resulting from this effort was *iasp91* (Kennett and Engdahl 1991). Subsequently, Kennett et al. (1995) constructed an improved model for the average P and S radial velocity profile of the Earth (*ak135*). The *ak135* model has proven very suitable for predicting the arrival times of a wide variety of seismic phases for use in event location and phase identification procedures, and the *ak135* model is presently used by both the NEIC and ISC.

For the flat Earth approximation, widely used in local earthquake location algorithms, many of the above corrections are unnecessary. The travel-time predictions can also, in many cases, be expressed in closed forms. For instance, for a two-layer velocity model with a source at the surface, the travel times for the direct, reflected, and refracted waves are given by

$$\begin{aligned} t_{\text{direct}} &= \frac{x}{v_1}; & t_{\text{reflected}} &= \frac{\sqrt{x^2 + 4h^2}}{v_1}; \\ t_{\text{refracted}} &= t_0 + \frac{x}{v_2} \end{aligned} \quad (7)$$

where x is distance, h is the depth of the layer boundary, v_1 and v_2 are the velocities above and below the layer boundary, $\vartheta = \arcsin(v_1/v_2)$ is the critical angle, and $t_0 = 2h \cos(\vartheta)/v_1$. Figure 3 shows the travel-time curves and various ray paths. Figure 3 also illustrates one of the major difficulties of the local earthquake location problem – despite the fact that the travel times are easily computed, one can generate a plethora of crustal phases, all arriving within a few seconds from each other. This can make phase identification difficult, especially around the crossover distances. It should be noted that ray tracing to obtain travel-time predictions could be still necessary if the velocity model becomes complicated, or the source is not in the uppermost layer of the model. Furthermore, the crust is the most heterogeneous part of Earth's interior, so 1D velocity models tend to do a poor job of adequately describing the local velocity structure. The result is increased nonlinearity, and it is not uncommon to have misfit surfaces with multiple local minima.

Depth Resolution

Until only recently the ISC and NEIC relied almost entirely on the times of first-arriving P phases to determine the locations of earthquakes that are observed globally, which for P rays bottoming in the lower mantle (teleseismic) the *ak135* travel times are particularly accurate. These agencies now use all later-arriving phases for earthquake location. In the absence of near-station phase data, direct teleseismic phases alone provide little depth

Earthquake Location,

Fig. 3 Ray paths and travel-time curves for a surface source in a two-layer velocity model. The refracted wave takes over the direct wave at X_{cross} , the crossover distance. The travel-time curves of the direct and refracted waves are *straight lines* with a slope of the slowness (inverse velocity) of the first and the second layer, respectively

resolution, as the derivative of travel time with respect to depth at teleseismic distances is only a small, slowly varying function. P-waves and S-waves that initially travel upward and reflect off of the Earth's surface before traveling to the recording station provide important constraints on event depth because their travel-time derivatives with respect to depth are opposite in sign to those of direct teleseismic phases, as illustrated in Fig. 4a. The surface-reflected phases are commonly referred to as “depth” phases. The trade-off between event depth and origin time is also avoided by the inclusion of depth phases. The arrival times of depth phases can either be used directly as an independent observation or the depth can be estimated based on differential pP-P times. Alas, due to interference with the direct phase, as well as potentially strong reverberations in the Earth's crust, a distinct depth phase is only reliably observed for events below approximately 50 km.

For local problems depth phases are little help as there is not enough separation between the direct P arrival and the depth phase, which

makes picking the depth phases extremely difficult, and therefore they are hardly ever used. However, if there are stations where both the direct (Pg) and refracted (Pb or Pn, traveling along the Conrad or the Moho discontinuities in the crust, respectively) phases are picked, they could provide sufficient resolution to constrain the depth as their travel-time derivatives with respect to depth have opposite signs. Figure 4b shows that at close distances the travel-time derivative of the direct phase changes rapidly, thus providing depth resolution. As a rule of thumb, stations closer than twice the event depth are needed to reliably constrain event depth.

Error Budget

The error budget in seismic location problems is traditionally described as the combination of “measurement” and “model” errors. The effect of errors due to ignoring the higher-order terms in the Taylor expansion in Geiger's method, except for some highly degenerate network geometries, is typically second order compared to the model and measurement errors.

Earthquake Location, Fig. 4 (a) Travel-time derivatives with respect to depth as a function of epicentral distance for a source depth of 600 km for direct teleseismic P and the teleseismic depth phases pP and sP. The direct teleseismic P phase cannot resolve the depth in itself as the depth derivative is a slowly varying function, but when depth phase picks are available, together they can resolve the depth. The inset shows that the depth phases pP and sP first reflected from the Earth surface and then travel along a similar ray path as the

direct teleseismic P phase. (b) Travel-time derivatives with respect to depth at local distances for a source depth of 15 km for the direct Pg and the refracted Pb and Pn from the Conrad and Moho discontinuities. At close distances the depth derivatives of the travel times of the direct phase are rapidly changing which provides depth resolution. Further away the direct and refracted phases together provide depth resolution owing to the opposite signs of their derivatives

Measurement Errors

Measurement errors describe the errors in picking the onset times of seismic phase arrivals and are typically modeled as normally distributed, zero-mean random variables. However, the distribution of travel-time residuals is skewed and suffers from heavy tails, which indicates that the

assumption of normally distributed errors is violated. Measurement errors also suffer from systematic errors as onset times of seismic waves traveling along the same ray paths are systematically picked late with decreasing signal-to-noise ratio. Furthermore, large earthquakes tend to produce more complex and emergent

Earthquake Location, Fig. 5 Waveforms of nuclear explosions carried out at the Nevada test site recorded at Elko, Nevada, about 400 km distance. The explosions were detonated within 15 km of one another. The waveforms are band-pass filtered between 1 and 3 Hz and shown with increasing event magnitude. While for the

two larger explosions the first-arriving Pn can be easily picked, for the two smaller explosions the first-arriving Pn is completely masked by noise, and the more energetic, later-arriving Pg could be erroneously picked as the first arrival

waveforms, due to their longer source time and larger volume of energy release. In such situations often a more energetic later arrival (e.g., *Pg* or *pP*) is picked as the first-arriving phase, instead of the emergent first arrival (e.g., *Pn* or *P*) whose onset may be obscured by noise. Figure 5 shows the waveforms for several nuclear explosions that are within 15 km of each other from the Nevada test site recorded at Elko, Nevada, about 400 km distance from the source. Note the similarity of the waveforms. While for larger magnitude events the first-arriving Pn phase is clearly seen, for smaller events the first-arriving Pn is obscured by noise, increasing the chance of picking the more energetic, but later-arriving Pg as the first arrival. Such phase identification errors have plagued event locations since the beginnings of instrumental seismology. Some location methods remove phases with ambiguous phase labels. Alternatively, one phase label can be randomly chosen from a list of candidates in hopes that averaging errors will mitigate event location bias (Engdahl et al. 1998).

Model Errors

Model errors are caused by travel-time prediction errors due to unknown velocity heterogeneities in the Earth and may introduce location bias. After phase identification errors are accounted for, model errors represent the most significant contribution to the error budget, especially at local and regional distances. Representing model errors as zero mean, Gaussian processes commonly lead to erroneous formal uncertainty estimates, as the distribution of model errors is not zero mean and is often multimodal. Because of their systematic nature (a velocity model will always produce the same travel-time prediction error along the same ray path), model errors can only be reduced by improved travel-time predictions that account for the 3D velocity structure of the Earth.

Another major contribution to the error budget originates from the assumption that observational errors are independent. Unfortunately most location algorithms, either linearized or not, make this very assumption. Velocity heterogeneities inadequately modeled by the underlying velocity

model will generate correlated travel-time prediction errors along similar ray paths. Thus, the assumption of independent errors is violated when rays sample the same velocity anomaly. Ignoring the correlation structure of the travel-time predictions results in both location bias and increasingly underestimated location uncertainty estimates.

Linearized Inversion Methods

All linearized location algorithms originate from Geiger's method (1910). The differences are typically in the details, such as how the inverse of the $\mathbf{G}$ matrix is obtained, what kind of weighting scheme is applied, and how the formal uncertainties are calculated. Expressed in a probabilistic framework and assuming independent, normally distributed data, linearized location algorithms maximize the likelihood function

$$\mathcal{L}(\mathbf{m}) = \exp \left\{ -\frac{1}{2} (\mathbf{d} - \mathbf{Gm})^T \mathbf{C}_d^{-1} (\mathbf{d} - \mathbf{Gm}) \right\} \quad (8)$$

where $\mathbf{C}_d$ is the data covariance matrix describing the uncertainties in the data (picking and model errors). Maximizing $\mathcal{L}(\mathbf{m})$ is equivalent to solving the equation

$$\mathbf{G}_w \mathbf{m} = \mathbf{W} \mathbf{G} \mathbf{m} = \mathbf{W} \mathbf{d} = \mathbf{d}_w \quad (9)$$

where $\mathbf{W} = \mathbf{C}_d^{-1/2}$ is the diagonal ($N \times N$) weight matrix. Some early location algorithms even make the quite simplistic assumption that all data variances are the same and collapse the data covariance matrix into a single scalar value.

Popular location algorithms solve Eq. 9 in various ways, such as standard least squares or calculating the general inverse of the $\mathbf{G}$ matrix. More recent algorithms tend to obtain the general inverse by singular value decomposition. Seismic arrays offer reliable estimates of back-azimuth (station-to-event azimuth) and apparent velocity (or more precisely, its inverse, the horizontal slowness vector) as a plane wave sweeps through the array. Several algorithms make use of the

slowness and back-azimuth measurements from arrays (Bratt and Bache 1988; Lienert and Havskov 1995; Schweitzer 2001). While early locators allowed only for first-arriving P and S phases, recent algorithms use most of the phases allowed for by the *ak135* model (e.g., Bratt and Bache 1988; Engdahl et al. 1998; Bondár and Storchak 2011). Several popular algorithms focus on the local earthquake location problem and use travel-time predictions from a local velocity model (Lee and Lahr 1972; Lienert and Havskov 1995; Schweitzer 2001). Almost all linearized location algorithms rely on one-dimensional velocity models or travel-time tables to obtain phase arrival-time predictions. To account for large-scale three-dimensional effects, the EHB algorithm (Engdahl et al. 1998) applies patch corrections, Bratt and Bache (1988) allows for local and regional source-station-phase-specific corrections as well as slowness-azimuth corrections, and the ISC locator (Bondár and Storchak 2011) is capable taking travel-time predictions directly from a 3D velocity model (Myers et al. 2010).

Uniform Reduction

One of the most successful location algorithms is Jeffreys' uniform reduction method (Jeffreys 1932). It was in use with minor modifications (Bolt 1960; Buland 1986) up until the introduction of a new location algorithm at the ISC (Bondár and Storchak 2011). Uniform reduction also relies on Geiger's method but solves the linear system of equations in an iteratively reweighted least-squares fashion. This means that each arrival time will get a weight depending on its residual. The weighting function is defined as

$$w(d) = \left[1 + \mu \exp \left\{ \frac{(d - m)^2}{2\sigma^2} \right\} \right]^{-1} \quad (10)$$

where μ , m , and σ are parameters estimated from the data (Jeffreys 1932). The weights are recalculated after each iteration. Hence, outliers get progressively smaller weights and their contribution to the final hypocenter will be

gradually reduced. However, Buland (1986) pointed out that the introduction of a nonlinear weighting function further complicates an already nonlinear problem. Indeed, while the uniform reduction performs robustly when only first-arriving phases are used, the fact that it treats all phases as equal makes using less reliably picked later phases in the location quite difficult.

Formal Uncertainty Estimates

One of the major advantages of Geiger's method is that a closed-form solution exists for formal uncertainties, defined by the a posteriori model covariance matrix. Let the general inverse of $\mathbf{G}_w$ obtained by singular value decomposition be $\mathbf{G}_w^{-1} = \mathbf{V}_w \mathbf{\Lambda}_w^{-1} \mathbf{U}_w^T$, where $\mathbf{\Lambda}_w$ is the ($N \times N$) matrix of singular values (eigenvalues), $\mathbf{U}_w$ is an ($M \times N$) orthonormal matrix, and $\mathbf{V}_w$ is an ($N \times N$) orthonormal matrix whose columns are the corresponding eigenvectors of $\mathbf{\Lambda}_w$. The model covariance matrix, $\mathbf{C}_m$, is written as

$$\mathbf{C}_m = \mathbf{G}_w^{-1} \mathbf{C}_d \mathbf{G}_w^{-1^T} = \mathbf{V}_w \mathbf{\Lambda}_w^{-2} \mathbf{V}_w^T \quad (11)$$

The model covariance matrix defines a four-dimensional error ellipsoid, whose projections provide the two-dimensional epicenter error ellipse and the one-dimensional estimates of depth and origin time uncertainties. The formal uncertainties represent the two-dimensional confidence interval for the epicenter and the one-dimensional confidence intervals for depth and origin time. These uncertainties are typically scaled to a specified percentile level (90 % or 95 %). In other words, the error ellipse scaled to the 90 % confidence level encompasses the region that contains the true location with 90 % probability. The surface of an error ellipsoid scaled to the p th percentile confidence level is defined as the hypocenters ($\mathbf{m}$) satisfying

$$(\mathbf{m} - \mathbf{m}_h)^T \mathbf{C}_m^{-1} (\mathbf{m} - \mathbf{m}_h) = \kappa_p^2 \quad (12)$$

where $\mathbf{m}_h$ is the point solution for the hypocenter and κ_p^2 defined by Jordan and Sverdrup (1981) as

$$\kappa_p^2 = M \hat{s}^2 F_p[M, K + N - M] \quad (13)$$

where F_p is an F statistic with M and $K + N - M$ degrees of freedom, M is the number of model parameters, N is the number of observations, and $\hat{s}^2$ is the a posteriori estimate of the variance scale factor given by $\hat{s}_e^2 = \frac{K \hat{s}_K^2 + \hat{s}_N^2}{K + N - M}$, where $\hat{s}_N^2$ is the a posteriori sample variance of residuals and $\hat{s}_K^2$ is the a priori estimate of $\hat{s}^2$ from previous experiments. Hence, the choice of K offers a balance between a variance scaling factor obtained from purely a posteriori residuals when $K = 0$ and from purely a priori estimates of data variances when K approaches infinity.

The formal uncertainties provide a statistical estimate of precision, but give no information about accuracy. Obviously, the precision of the measurement increases with the number of data, resulting in a smaller error ellipsoid. However, systematic measurement and model errors may introduce bias, which cannot be accounted for by the error ellipsoid. The accuracy of the measurement is the deviation from its true value and can only be measured when ground truth information is available.

Correlated Errors

All the equations above rely on the assumption that the errors are independent. When correlated travel-time predictions are present, the data covariance matrix $\mathbf{C}_d$ is no longer diagonal. The correlation structure implies that linear combinations of residuals may exist. In this case $\mathbf{W}$ is no longer defined as a diagonal weight matrix, but a projection matrix that orthogonalizes the data set and projects redundant observations into the null space (Bondár and McLaughlin 2009). Consequently, instead of the total number of observations, only the number of independent data contributes to the calculation of the formal uncertainties. This effectively decouples the size of the error ellipsoid from the number of correlated observations, thus preventing the error ellipsoid shrinking beyond control when increasing number of redundant observations are added. Heavily unbalanced, dense networks are prone to have enough similar ray paths to introduce location bias. Accounting for correlated travel-time

predictions not only produces more reliable formal uncertainty estimates, but also reduces location bias.

Nonlinear Methods

Poor network configuration and/or the use of a model with discontinuous travel-time derivatives can result in multiple local minima in the arrival-time misfit function, which is problematic for algorithms based on Geiger's method. Numerous strategies have been developed to mitigate the tendency of Geiger's method to get "stuck" in a local minimum. Most commonly, a number of widely varying starting locations are iterated to convergence, and the solution with the lowest misfit is selected. However, there is no guarantee that the global minimum is found and the formal uncertainty at the chosen hypocenter is not an accurate representation of the non-Gaussian misfit function.

A number of nonlinear inversion procedures have been developed with the goal of reliably finding the global minimum in the misfit function (i.e., the best location) and better representing location uncertainty. The vast majority of nonlinear methods use a strategy of explicitly sampling the misfit function on a discrete grid of points (grid search). If the sample points provide a high-fidelity representation of the misfit function, then it is straightforward to find the hypocenter, which is the global minimum in the misfit function.

Using grid search, it is only slightly more difficult to determine probability contours that define hypocenter uncertainty. Sambridge and Kennett (1986) provide a succinct description of how misfit may be mapped to probability. Assuming Gaussian data errors, the likelihood at hypocenter grid points, $\mathcal{L}(\mathbf{m})$, that satisfy the inequality

$$\frac{[\mathcal{L}(\mathbf{m}) - \mathcal{L}(\hat{\mathbf{m}})]}{\mathcal{L}(\hat{\mathbf{m}})} \leq \frac{\chi_4^2(p)}{(N - M)} \quad (14)$$

are within the p probability region, where p ranges between 0 and 1. The number of

hypocenter parameters ($M \leq 4$) determines the order of the chi-squared function (χ^2), and $\hat{\mathbf{m}}$ is the global minimum of the misfit function. The chi-squared function is divided by the degrees of freedom, which is the number of observations (N) minus the number of free parameters (M). The shape of the probability region determined in this way is nonparametric, which can provide an accurate assessment of location uncertainty. However, the nonparametric form can be difficult to summarize into a compact form that is convenient for distribution in a bulletin format.

Obviously, a grid search on hypocenter parameters is the most straightforward approach to map the misfit function. However, a global grid search can have computational limitations, even in the case of single-event location. For example, a grid with 1 km spacing on Earth's surface extending to a depth of 35 km (*ak135* crustal thickness) and sampling 0.1 s for 1 min would result in a grid of over 10^{13} points. Even if travel times were computed in a microsecond, a location based on 100 arrival times would require years to compute on a single processor. Clearly, strategies to reduce the grid dimensions are needed in order to make a grid search on all four hypocenter parameters practical.

Sambridge and Kennett (1986) limit the search domain by determining hypocenter bounds based on the station locations at which P-waves arrive first, S-wave minus P-wave arrival time, and plausible ranges in wave speed. In this case the domain of the grid search is determined by the data set, so computational demand can vary greatly. However, if the search domain were limited to an epicenter domain of 100 km by 100 km by 35 km by 60 s on a km spatial grid and a 0.1 s time grid, then computational time can be a few minutes on a single processor.

Rodi (2006) describes an adaptive grid search method that further reduces computational time by starting with a course grid and progressively densifying the grid in the neighborhood of points where the misfit function is lowest. Adaptive gridding has the benefit of enabling an arbitrarily fine grid in the neighborhood of the event, which

removes limitations on hypocenter accuracy that is inherent for a fixed grid.

Sambridge and Kennett (2001) use a natural neighbor approach to further refine the sampling strategy. The natural neighbor method starts with a random sample in hypocenter space. More random samples are then generated in the neighborhood of hypocenter samples with the lowest misfit values. This process is iterated until a global minimum is found. Similar to the grid search method, the misfit function can be contoured to assess location uncertainty. As will be discussed further, the misfit may also be used to guide numerical integration of multidimensional probability of the hypocenter, which provides a high-resolution estimate of the hypocenter volume.

It should be noted that features in the misfit function, including the global minimum, can be missed if the spacing of the sample points is too large. For example, if a grid with 10 km spacing is used, then a feature in the misfit function with spatial dimension of a few km might not be sampled. This is particularly problematic for adaptive grid approaches, for which computational gains are derived from a coarse starting grid. The safest practice is to initialize sampling with spacing smaller than the expected dimension of location uncertainty. That way the edges of the depression in the misfit function will be reliably sampled.

Estimating the probability density function of the hypocenter via stochastic sampling can more accurately characterize the probability volume and can, in some instances, improve computational efficiency. Lomax et al. (2000) introduce the Metropolis-Gibbs method to sample the a posteriori location probability density function. The Metropolis-Gibbs method begins with a starting hypocenter (state), which is commonly selected to be the location of the station at which the first P-wave arrived. A new hypocenter is proposed based on a random perturbation of the current state. If the probability of predicted data (weighted data fit) is higher at the proposed hypocenter, then the proposed hypocenter becomes the new "state." If the probability is lower at the proposed hypocenter, then it is accepted at a rate proportional to the ratio of the probabilities at the

proposed hypocenter and the current state. If the procedure of proposing a new hypocenter adheres to the critical balance condition, which requires reciprocity of probability in the proposal processes, then the series of accepted states comprise a Markov chain, for which each state is a random sample of the multidimensional hypocenter probability function. Therefore, high sample density equates to high probability. Many Markov chains with widely varying starting locations can be used to ensure robustness (Myers et al. 2007). The process of proposing, accepting, and rejecting new hypocenters typically finds the neighborhood of the global minimum in a few hundred iterations. The process is iterated thousands of more times to adequately characterize hypocenter probability, but the number of forward calculations is still orders of magnitude fewer than in a full grid search. Sample density may be contoured to characterize the nonparametric probability volume over hypocenter space. Alternatively, summary statistics (e.g., probability ellipses) may be computed by assuming that the samples are drawn from an analytical distribution (e.g., Gaussian).

Event Location with 3D Velocity Models

As discussed in the section on model errors, travel-time prediction errors are particularly problematic because they are repeatable, not random. This property of model error can result in a similar vector shift (bias) in hypocenter parameters and unrepresentative location uncertainty estimates (Bondár and McLaughlin 2009). Accounting for data covariance can mitigate the effects of model error, but a more accurate location and smaller uncertainty bounds can be achieved by improving travel-time prediction accuracy with improved models of seismic velocity. Practical application of 3D models depends greatly on the distance domain of the network: teleseismic, regional, or local.

Teleseismic

Teleseismic travel times can be accurately computed by integrating slowness along a ray that is

computed using a 1D model. In other words, the derivative of teleseismic travel time with respect to observed variations in lower mantle velocity is approximately linear. As a result, ray templates could be used to compute travel times on the fly. However, the most common approach is to precompute differences between travel times for a 3D and a 1D model at a fixed event depth. The travel time for the 3D model may then be approximated by using the 3D-1D model difference as a correction to the computationally efficient travel-time lookup for the 1D model. For example, a zero-depth correction surface may be applied to locate events throughout the crust. Travel-time corrections are attractive at teleseismic distance because deviations from 1D travel times vary slowly and interpolation of corrections is accurate even when points of precomputation are on the order of 100–200 km apart. Studies of improvement in epicenter accuracy generally find that average error can be reduced from approximately 15 km to approximately 8 km (e.g., Yang et al. 2004).

Regional

Due to strong velocity anomalies, minimum-time rays turning in the upper mantle can differ significantly for 3D and 1D models. Ray shooting techniques have been used to compute regional travel times. Shooting methods iterate on the direction and inclination of a ray leaving the event until the ray hits the station. However, a geometrical ray may not exist for some paths, resulting in “shadow zones” where travel time is not defined, but diffracted waves may be observed. Shadow zones cause significant difficulty for location algorithms because they are discontinuities in the domain of the travel-time calculation. Shadow zones can be avoided by using ray bending methods (e.g., Zhao and Lei 2004; Simmons et al. 2012), where ray endpoints are fixed and the ray is iteratively bent to find the least-time path. Bending methods have the advantage of providing an approximation to the travel time of diffracted waves, thus providing a travel time between any two points. Although regional ray paths and travel times can be

computed in about one-half second on current computers, real-time location may require precomputation. Precomputation approaches at regional distance are the same as those described for teleseismic phases, but the grid spacing must be smaller in order to capture strong gradients and first-order discontinuities in the travel-time corrections. Myers et al. (2010) achieve milli-second regional travel-time computation for Pn and Sn phases by parameterizing upper mantle velocity as a linear gradient, which enables flexible, on-the-fly implementation in a real-time location procedure. However, this approach is not applicable for rays interacting with velocity discontinuities at approximately 410 and 660 km depth.

Because crust and upper mantle velocity anomalies can be large compared to anomalies in the lower mantle, regional travel-time errors for 1D models can be many times larger than those at teleseismic distances. Epicenter error can be reduced from approximately 20 km on average for a 1D model to approximately 6–8 km for a 3D model (e.g., Ritzwoller et al. 2003; Yang et al. 2004; Flanagan et al. 2007; Myers et al. 2010).

Local

Velocity anomalies are largest in the crust, and important velocity discontinuities can be unique to local study areas. Unless local velocity models are highly smoothed, numerical solutions to the equation of a propagating wave front are the best approach for local travel-time calculations (e.g., Hole and Zelt 1995; Rawlinson and Sambridge 2004). Eikonal solutions are computationally expensive and require precomputation from each station of the network to a dense 3D grid of predefined points. Relying on travel-time reciprocity, a travel time from any hypothesized event location to each station of the network can be computed using 3D interpolation of the travel-time grid. The derivative of travel time with respect to event location is appreciably nonlinear at local distances, making nonlinear locators the best option (e.g., Lomax et al. 2000).

Multiple Event Location Methods

Simultaneous analysis of arrival times that are associated with many events provides information that can help to constrain unknowns beyond those of the event locations. Unknowns such as corrections to travel-time predictions, arrival-time measurement precision, and phase names may be inferred if the data set contains sufficient information. Because the unknown parameters include travel-time prediction corrections, uncertainties for each datum, and hypocenters, it is clear that the number of unknowns in the most general formulation of the multiple-event inversion will always outnumber the data. Therefore, the most general formulation will always be underdetermined. The choice of parameters to be included in the inversion and the approaches to constrain the inversion distinguish the various multiple-event applications.

Douglas (1967) introduced multiple-event location with the joint epicenter determination (JED) formulation. If the data set contains one phase type, the multiple-event formulation is

$$d_{ij} = \Delta T_i^o + \frac{\partial t_{ij}}{\partial z_i} \Delta z_i + \frac{\partial t_{ij}}{\partial y_i} \Delta y_i + \frac{\partial t_{ij}}{\partial x_i} \Delta x_i + \Delta s_j \quad (15)$$

where i specifies the event, j specifies the station, d is the travel-time residual, z is event depth, y and x are local event coordinates in the direction of latitude and longitude, T^o is event origin time, t is phase travel time, and S is a station-specific travel-time correction also called station correction. The linear system of equations is iterated to convergence. There is a need to impose constraints on the solution to Eq. 15 to remove ambiguity in the determination of the station terms. S. Douglas (1967) chose to force the sum of station corrections equal to zero, which remedies a trade-off between a shift in origin time of all events and the average station correction. Zero-mean station corrections make the implicit assumption that base-model travel-time prediction errors are zero mean. Still, absolute locations

can be poorly constrained if events are tightly clustered and event-station distances are large. Douglas (1967) suggested determining station corrections based on the residuals of one event whose hypocenter parameters are assumed known. All other events are then located relative to the fixed event. This technique becomes known as the master event location method and is frequently used to constrain absolute locations in an event cluster.

A number of methods improve the robustness and efficiency of solving the multiple-event system of equations. Dewey (1972) expanded on JED to include other phases and data weighting based on estimated pick uncertainty. Dewey's formulation is the widely used Joint Hypocenter Determination (JHD) method. Jordan and Sverdrup (1981) and Pavlis and Booker (1983) employed matrix projection operators to optimally compute unbiased estimates of station corrections. Jordan and Sverdrup (1981) solved the system of equations including event locations and station corrections in one iteration (hypocentroidal decomposition, HDC). Pavlis and Booker (1983) located each event independently, determined unbiased station corrections based on residuals, and repeated the process until convergence (progressive multiple-event location, PMEL). HDC is better suited for use with regional and teleseismic networks for which partial derivatives with respect to event location are relatively linear. PMEL has the advantage being more robust to highly nonlinear derivatives, which is generally true at local distances.

Recognizing the extreme precision of relative arrival times afforded by waveform correlation, Got et al. (1994) directly utilized differential arrival times to obtain highly precise relative event locations. The method minimizes the difference between observed and predicted differential arrivals. Thus, the approach is popularly referred to as double difference. Waldhauser and Ellsworth (2000) extended the double difference method to larger regions by introducing an inter-event length over which the implicit station/phase corrections decorrelate (HypoDD program).

Computational limitations prevent application of HypoDD to an arbitrarily large data set.

Myers et al. (2007, 2009) introduced a Bayesian nonlinear inversion framework to multiple-event analysis (Bayesloc). The nonlinear Markov chain Monte Carlo method enables Bayesloc to simultaneously assess the joint posterior distribution spanning event locations, travel-time corrections, phase names, and arrival-time measurement precision. Myers et al. (2011) demonstrated that Bayesloc can be applied to data sets of tens of thousands of events and millions of arrivals because the solution does not involve direct inversion of a matrix and computation demands grow linearly with the number of arrivals.

Multiple location methods when used properly will ordinarily produce precise relative earthquake locations. However, these locations will almost always have an unresolved bias, depending on the scale of lateral heterogeneity in the underlying Earth model. Lateral heterogeneity, especially in subduction zones, will also set limitations on the maximum inter-event distance when using multiple-event location methods. If the inter-event distances are too large, then travel-time predictions from events to stations will not be precisely correlated, potentially degrading the precision of relative locations.

Summary

The history of earthquake location methods is intertwined with the evolution of computers. Even though Geiger formulated the problem just 4 years after the great San Francisco earthquake, it was not implemented in routine operations until the first mainframe computers became available. Similarly, direct search methods became computationally viable only in the late twentieth century. Before the 1980s location algorithms typically were able to deal with a few dozen first-arriving P phases; nowadays, owing to the much higher station density, it is not uncommon that an event is reported with several

thousands of associated phase arrivals. Even just a decade ago, it would not have been possible to perform near-real-time waveform correlation and double difference location in a dense local network (Waldhauser 2009) or simultaneously relocate thousands of globally distributed events with a multiple location algorithm (Simmons et al. 2012). Hence, it can be expected that earthquake location methodologies will continue to evolve with ever-increasing computational power.

Introduction

The magnitude of an earthquake (see ► [Earthquake Mechanisms and Tectonics](#)), or of other types of seismic events such as explosions, rock bursts, cave collapses, mining, or other by human activities induced events, is a number that characterizes the relative size of the event or of the amount of elastic seismic wave energy released by it. Therefore, the earthquake magnitude is, together with ► [Earthquake Location](#), the most important and most frequently determined seismic source parameter. Usually, magnitude values are based on the instrumental measurement of the maximum ground motion recorded by seismographs at Seismic Stations, ► [Seismic Networks](#), or ► [Seismometer Arrays](#), sometimes for a particular wave type and in a specific frequency range. However, these measured values have to be corrected for the decay of amplitudes with source distance and depth due to geometric spreading and attenuation during the propagation of seismic waves so as to become a representative value for the size of the seismic source or of the radiated seismic energy and thus of the related strength of seismic shaking. These correction or calibration values are usually given as formulas or in tabulated form. However,

sometimes magnitude values are also attributed to seismic events based on field observations of earthquake effects such as length and displacement of related surface ruptures or macroseismic effects such as earthquake damages in the near source area (see [Earthquake Intensity and Intensity Scales](#) by Musson and Cčić 2011; Grünthal 2011), using correlation relationships with instrumentally measured magnitudes. So derived macroseismic magnitudes M_{ms} are particularly important for the analysis and statistical treatment of historical earthquakes (see 3.2.6.6 in Bormann et al. 2013) but in this essay only instrumentally determined magnitudes will be considered.

The first paper on earthquake magnitude was published by Charles F. Richter (1935). Therefore, often the term *Richter scale* is used as a synonym. Yet, this may be incorrect, especially for very large earthquakes and magnitudes measured at so-called teleseismic distances of more than 1,000–2,000 km away from the source for which the original Richter scale is not applicable. Richter's aim was (quote):

In the course of historical or statistical study of earthquakes in any given region it is frequently desirable to have a scale for rating these shocks in terms of their original energy, independently of the effects which may be produced at any particular point of observation.

The term *magnitude scale* was recommended to Richter by H.O. Wood in distinction to the term *intensity scale* which classifies the severity of earthquakes mainly on the basis of felt shaking or damage manifestations at different localities.

Richter compared earthquake records in Southern California made at different distances and azimuths from the earthquake source with a standard type of short-period horizontal component Wood-Anderson (WA) torsion *seismometer*. All these instruments had an identical frequency response (see red curve in Fig. 3 and ► [Seismic Instrument Response, Correction for](#)) and a static magnification, according to the manufacturer, of 2800. Many stations of the Southern California seismic network had already in the early 1930s been equipped with such seismometers. Figure 1 shows on top a typical WA-record of a near

According to this original definition of the local magnitude scale $M_L = M_L$ by Richter (1935), only the *maximum trace amplitude* B in mm as recorded in standard records of a Wood-Anderson seismometer is measured, i.e.: $M_L = \log B(WA) - \sigma(\Delta)$

⇒ no period T is measured, and **NO CONVERSION** to “ground motion” amplitude A by correcting for the frequency-dependent seismograph magnification is made.

$$M_L = \log B(WA) - \sigma(\Delta)$$

$$M_L = 1.36 + 3.46 = 4.82$$

Calibration function $\sigma_L(\Delta) = -\log A_0$ for local magnitudes M_L according to Richter (1958). A_0 are the amplitudes in mm recorded by a Wood-Anderson Standard Torsion Seismometer from an earthquake of $M_L = 0$. Δ - epicentral distance in km.

Δ (km)	$\sigma_L(\Delta)$	Δ (km)	$\sigma_L(\Delta)$	Δ (km)	$\sigma_L(\Delta)$	Δ (km)	$\sigma_L(\Delta)$
0	1.4	90	3.0	260	3.8	440	4.6
10	1.5	100	3.0	280	3.9	460	4.6
20	1.7	120	3.1	300	4.0	480	4.7

Earthquake Magnitude Estimation, Fig. 1 Summary of the classical procedure of measuring M_L . Note that the letter B was given here to record trace amplitudes,

highlighting that they were not converted to ground motion displacement amplitudes A (Modified copy of Fig. 3.28 in Bormann et al. 2013; © IASPEI)

earthquake. By plotting, for many events, the logarithm of the recorded maximum trace amplitudes A_{max} over the *epicentral distance* Δ (see ► [Earthquake Location](#)), Richter derived empirically average distance-dependent calibration values $\sigma(\Delta)$. They were needed in order to compensate for distances up to 600 km for the decay of the reference amplitude A_0 with distance from the seismic source. It holds $\sigma(\Delta) = -\log A_0$. Tabulated values for $\sigma(\Delta)$ are given in Fig. 1. Adding them to the logarithm of the maximum trace amplitude $B(WA)$ of a seismic event recorded by a WA seismograph (see Fig. 1) makes the event amplitudes measured at different distances comparable and yields the event magnitude. Moreover, the corrected amplitudes for different events are then indicative for the differences in event size. Accordingly, the local magnitude M_L has been defined as

The magnitude of a shock is ... the logarithm of the calculated maximum trace amplitude, expressed in microns, with which the standard short-period torsion seismometer ... would register that shock at an epicentral distance of 100 km. (Richter 1935)

This implies that an amplitude of 1 mm on the WA seismogram corresponds to a magnitude 3 earthquake and this provides the anchoring of the scale.

Figure 1 illustrates the determination of the local magnitude M_L according to this procedure. Since then several other magnitude scales have been developed, pioneered with three publications by Beno Gutenberg (1945a, b, c). He was interested in the use of the magnitude concept for classifying the size of earthquakes worldwide, based on *body-wave* and *surface-wave* measurements also at teleseismic distances. These magnitudes were later termed m_B and M_S

by Gutenberg and Richter (1956) who also published in this paper calibration values for three types of body waves: (1) in propagation direction oscillating pressure waves P, (2) PP waves which are P waves that have been reflected back on the Earth surface at half way distance between the source and the seismic station and (3) S waves, which are slower travelling shear waves of larger amplitudes (see Fig. 1) that oscillate perpendicular to the direction of wave propagation. Yet, already Gutenberg and Richter realized that their original dream of a unique size scaling of earthquakes was not achievable with magnitude scales based on different types of seismic waves, measured at different source distances and frequencies. Although they mutually scaled M_L , m_B , and M_S to agree at values around 6.5 these magnitudes differ elsewhere, up to about one magnitude unit (m.u.) (Fig. 15). This problem became even more obvious when seismographs operating at much wider, or narrower, ranges of frequency with much higher amplification of ground motion than available at Gutenberg's and Richter's time, made it possible to measure magnitudes up to 9.5 and down to less than zero. Magnitudes measured at periods much less than the duration of earthquake rupture or of another seismic waves generating process were then found to systematically underestimate the overall earthquake size and energy release and thus also its magnitude. This effect is often referred to as "magnitude saturation." The controlling parameters are outlined in section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#).

It often occurs that different agencies publish magnitudes with the same nomenclature although they had been measured with different filter procedures within different measurement time windows and corrected with different calibration functions. Thus it could happen that the first available values of the most widely measured short-period teleseismic m_b magnitude (see section [Body-Wave Magnitudes](#)) for the great devastating Sumatra-Andaman tsunami generating earthquake of December 26, 2004, ranged between 5.7 and 7.5 (Bormann et al. 2007, 2009).

In view of magnitudes being logarithmic numbers this corresponds to a difference in estimated short-period seismic energy release of this event by a factor of almost 2,000 times. Moreover, even the largest of these m_b values, measured around 2 s period for a rupture with an estimated duration of 500–600 s, saturated already at 7.5. This is almost two magnitude units less than the much later available largest *moment magnitude* value (see section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#)) of $M_w = 9.3$ and explains the initial underestimation of the size and related hazard of this earthquake. These differences become less for smaller earthquakes but remain nevertheless often still unacceptably large (Granville et al. 2005; Bormann et al. 2007). They are a possibly source of bias or large data scatter when such data, if they enter catalogs, are used in estimates of magnitude-dependent [Earthquake Recurrence](#) frequency, or of Deterministic Seismic Hazard Analysis or [Probabilistic Seismic Hazard Analysis](#) in terms of [Seismic Hazard: Ground Shaking](#).

The confusion that is sometimes associated with apparently well-established common practise of magnitude determination has highlighted the urgent need for:

- (a) Internationally agreed standards of measurement procedures for the most widely used types of magnitudes and
- (b) Wider published and easily accessible critical reviews on the physical basis of the diverse approaches to magnitude measurements, their potentials, biases, and mutual relationship.

The former issue has been taken up by an international Working Group on Magnitude Measurement of the Commission on Seismological Observation and Interpretation (CoSOI) of the International Association of Seismology and Physics of the Earth's Interior (IASPEI). It resulted in the adoption of IASPEI (2013) resolution No. 1 (Fig. 2).

The second issue has been elaborated in detail in Chap. 3 of the second, now electronic edition

IASPEI Resolutions

2013 Scientific Assembly, Gothenburg, Sweden

Resolution 1: Magnitude Standards

RECOGNISING the importance of the magnitude standards proposed by the Working group on Magnitude measurements of the Commission on Seismological Observation and Interpretation and published in the New Manual of Seismological Observatory Practice (second edition),

IASPEI

RECOMMENDS the station and network operators and data centres to adopt these standards in day to day operations, and

ENCOURAGES the developers of waveform processing programmes to incorporate these standards within their software packages.

Earthquake Magnitude Estimation, Fig. 2 IASPEI resolution 2013 on magnitude measurement standards (© IASPEI)

of the IASPEI New Manual of Seismological Observatory Practice (NMSOP-2; <http://nmsop.gfz-potsdam.de>; Bormann et al. 2013) and related complementary NMSOP publications. Therefore, the focus will be in the following on the principles, procedures, and advantages of the recommended new measurement standards for the most important types of classical magnitudes. This will be complemented by an introduction into the more physically defined and nearly non-saturating seismic moment and energy broadband magnitudes, M_w , and M_e , as well as into most recently developed faster proxy estimates for these magnitudes that are applicable in (near) real-time earthquake and tsunami early warning schemes. But beforehand the essential features of earthquake rupture and the radiated seismic wave spectrum as well as their controlling parameters are explained in order to understand the often striking differences between different magnitude scales. For any further details, also on other types of magnitude, readers should consult NMSOP-2.

Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy, and Related Magnitudes

An earthquake is a shaking of the Earth that is either *tectonic* or volcanic in origin or caused by collapse of cavities in the Earth. A tectonic earthquake is caused by *fault slip*. Faults are fractures or fracture zones in the Earth along which the two sides have been displaced relative to one another parallel to the fracture. The friction between the rock masses adjacent to the fault usually prevents slip or creep along the fault even under tectonic stress load. Thus stress can accumulate until the breaking strength of the fault material is reached and fault rupture occurs. During the fault slip part of the accumulated tectonic stress is released. The difference between the stress in the source volume before and after the fault slip is called *stress drop* $\Delta\sigma$. How much stress can be accumulated and released also depends on the density of the rock material along the fault and its resistance against shearing, which is usually expressed by

its *shear modulus* μ , also termed *rigidity*. The frictional conditions, μ and $\Delta\sigma$ also control the velocity or speed of the fault rupture and thus the *rupture duration*, which varies between the smallest and the largest earthquakes between about 1/100th of a millisecond to several minutes for rupture lengths between centimeters and more than 1,000 km with related magnitudes between about -2 to 9.5 . An approximate relationship between non-saturated magnitude M and average rupture duration τ_{rup} has been given by Bormann et al. (2009):

$$\log \tau_{\text{rup}} \approx 0.6M - 2.6. \quad (1)$$

Thus, earthquake ruptures of magnitude $M = 4, 5, 6, 7, 8$, and 9 would roughly last on average 0.4 s, 1.6 s, 6 s, 25 s, 100 s and 400 s, i.e., τ_{rup} increases by about by a factor of four per magnitude unit. However, depending on the rigidity of the material in the source volume and the related stress conditions the rupture velocity v_{rup} and thus τ_{rup} of individual earthquakes may deviate from this average by a factor of about 2 – 3 shorter or longer (see Fig. 5).

As shown in section [Magnitude Scales and the New IASPEI Measurement Standards](#) the size estimates of different magnitude scales may differ for the same earthquake. These differences (or none) usually depend on the magnitude itself. They can only be understood when considering – besides possible differences in the time windows within which magnitude is measured on the seismic record – how the measurement parameters amplitude and period, used by these scales, differ in relation to the radiated seismic source spectrum.

Source spectra observed in the far field, i.e., several wavelengths away from the rupture, depend on the rupture size, $\Delta\sigma$, the related v_{rup} and the ratio between released seismic wave energy E_s and seismic moment M_0 . The scalar seismic moment M_0 of a shear rupture is proportional to the constant displacement plateau amplitude u_0 of the radiated source spectrum and defined as

$$M_0 = \mu \bar{D} A \quad (2)$$

where $\bar{D}$ = average slip over the fault and A = rupture area. All these values, with the exception of the rigidity μ , can be estimated via model assumptions from measured spectral displacement plateau amplitudes and the corner frequency f_c of the source spectrum (Baumbach and Bormann 2011). Therefore, it has been suitable to scale the displacement spectra in Figs. 3 and 4 to seismic moment and the related velocity spectra to the moment rate, i.e., the time derivative of M_0 .

Fig. 3 shows this for an average shear rupture model of equal stress drop for events of different size and Fig. 4 for earthquakes of equal size in terms of seismic moment but different in stress drop. For model details see Bormann et al. (2009), but the fundamentals can be understood with reference to these figures without knowing these details.

M_0 increases linearly with the product $\bar{D} A$, also termed *earthquake potency*, which is a static measure of the overall earthquake “size,” But the potency does not account for differences in rupture velocity or stress drop and thus related differences in the radiated frequency content and amount of seismic energy for a given M_0 . None the less, this lead Kanamori (1977) to propose, via relationship (2) and by assuming constant average values of μ and $\Delta\sigma$ and thus of the ratio E_s/M_0 , a non-saturating “ w = work” or moment magnitude scale, termed M_w . It is most consistently determined by the recommended IASPEI (2013) standard way of writing the original Hanks and Kanamori (1979) formula, and reads

$$M_w = (\log M_0 - 9.1)/1.5. \quad (3)$$

M_0 and thus M_w will not saturate with growing rupture size provided that they are measured via the plateau amplitude u_0 of the radiated displacement source spectrum. This requires, however, to measure u_0 at frequencies much smaller than the corner frequency f_c , i.e., at wavelengths larger than the length of the source rupture.

M_0 calculations are nowadays routine at major seismological centers, either by measuring the displacement amplitude u_0 on the long-period asymptote (plateau) of the source spectrum,

Earthquake Magnitude Estimation, Fig. 3 Theoretical source spectra of radiated displacement (*left*) and velocity amplitudes (*right*) scaled to seismic moment M_0 , respectively seismic moment rate dM_0/dt in relation to the period ranges within which the IASPEI (2013) standard magnitudes are measured (see section [Magnitude Scales and the](#)

[New IASPEI Measurement Standards](#)). The frequencies at which the plateau amplitudes, respectively M_0 have dropped to about 70 % of their plateau values are termed corner frequencies f_c (Modified Fig. 1 from Bormann et al. 2009, BSSA © Seismological Society of America)

which is proportional to M_0 after correcting for the source radiation and wave propagation effects (as done in Fig. 3), or, as a spin-off of seismic moment tensor calculations (see ► [Moment Tensors: Decomposition and Visualization](#)), by fitting long-period synthetic seismograms for different source models best to long-period filtered real seismic records, using wavelengths that are larger than the rupture length. But differences in procedures are the reason that not all yield fully compatible and non-saturating M_0 and M_w

values. For example, for the great 2004 Sumatra-Andaman M_w 9.3 earthquake the reported values for M_w differed up to about one magnitude unit (m.u.). The most important procedure, elaborated by Dziewonski et al. (1981), forms, with some later modifications, the computational basis for the authoritative Global Centroid Moment Tensor Catalog. Values for all major earthquakes with $M_w > 5.5$ are regularly published by the GCMT project (<http://www.globalcmt.org/CMTsearch.html>) and available

Earthquake Magnitude Estimation, Fig. 4 Source spectra for the same model as in Fig. 10 but for earthquakes of the same size yet different in stress drop

(in MPa) (Copy of Fig. 2 from Bormann and Di Giacomo 2011 © Springer; with kind permission from Springer Science + Business Media)

within about 2 h after the event. Less frequently and incomplete the GCMT catalog now also reports M_w values down to about 4.5. Regional centers, such as Swiss Earthquake Service, provide – with larger time delay – reliable moment tensor and M_w solutions also down to significantly smaller values, e.g., when dense quality networks close to the source are available, down to $M_w \approx 3.0$ (Braunmiller et al. 2002).

A new method for rapid non-saturating moment tensor and M_w estimates is based on very long-period W-phase observations between the P- and S-wave arrivals (Kanamori and Rivera 2008 and Sect. 3.2.8.6 in Bormann et al. 2013). First real-time implementations are operational at the U.S. Geological Survey’s NEIC (Hayes et al. 2009) as well as at the GFZ Potsdam and the Indonesian Tsunami Early Warning System (InaTEWS) since 2011.

The question arises why the radiated displacement amplitude spectra in Figs. 3 and 4 are flat at

frequency much lower and drop strongly with frequencies higher than f_c . As in optics, lower frequencies with wavelengths larger than the object, in our case the causing rupture, cannot resolve any smaller detail of the rupture. They “see” the earthquake only as an undifferentiated “point source,” integrating over the whole rupture length. Accordingly, there is no difference in the respective displacement amplitudes at frequencies $f \ll f_c$. In contrast, higher frequencies with wavelengths smaller than the rupture length are radiated by smaller rupture patches. Their generated displacement amplitudes are lower the smaller the size of these patches. This explains the rapid decay of amplitudes towards higher frequencies. The length of rupture can be estimated from f_c via some model assumptions and corrections made about the seismic source and the wave propagation effects.

The most common source spectra model is the ω^{-2} model, in which the displacement

amplitudes decay at frequencies $f = \omega/2\pi \gg fc$ with the second order, as in Figs. 3 and 4. However, there are other models, where the amplitudes drop steeper, with third or even higher order. This is also observed, besides the ω^{-2} decay, in empirical data. If the linear dimensions of the rupture increase with increasing size of the earthquake, fc moves towards lower and lower frequencies. Average values of fc for magnitude 4 earthquakes are on average around 2.5 Hz and for a magnitude 8 earthquakes around 0.02 Hz. However, as seen from Fig. 4, for a given scalar seismic moment and thus static measure of earthquake “size”, fc depends also on $\Delta\sigma$ in the source volume. Depending on μ in the source volume and the ambient stress conditions, $\Delta\sigma$ may vary by 3 to 4 orders of magnitude. Since $f_c \sim \Delta\sigma^{1/3}$ (Brune 1970) this may result in differences of fc for equal M_0 by a factor of 10 or even more.

These possible modifications notwithstanding, Figs. 3 and 4 explain why any magnitude scale which measures amplitudes at frequencies much higher than fc will underestimate the earthquake size in terms of seismic moment. The same applies with respect to the underestimation of earthquake “strength” in terms of released seismic energy, with the latter being proportional to the squared seismic moment rate, when the largest ground motion velocity $V_{\max}$, or $(A/T)_{\max}$, is measured at frequencies much higher or lower than f_c (see the right hand panels of Figs. 3 and 4). On average, spectral underestimation with respect to M_w begins to become significant for short-period (1 Hz) m_b and M_L already at values >5.5 – 6 , in contrast to the two surface-wave magnitudes measured at periods around 20 s, termed $M_S(20)$, respectively <60 s, termed $M_S(\text{BB})$, and the P-wave broadband magnitude $mB(\text{BB})$ that is measured at $T < 30$ s, for which spectral saturation begins only at $M_w > 7.5$ – 8 . However, $M_S(20)$, measuring $\log(A/T)$ around 20 s, and not $A_{\max}$ or $V_{\max}$, is expected to be smaller than M_w also for events with $M_w < 6$ – 6.5 . This is in agreement with empirical data in Figs. 7, 15, and 17 as well as Eq. 17.

Similarly to formula (3), the recommended standard formula for calculating the energy

magnitude M_e proposed by Choy and Boatwright (1995) is now written as

$$M_e = (\log Es - 4.4)/1.5. \quad (4)$$

with Es in Joules. Modern velocity-broadband records allow nowadays to estimate radiated seismic wave energy Es by integrating squared velocity amplitudes over a wide range of periods around the peak values of the velocity spectrum (Fig. 3, right hand panel), and correcting them for wave propagation effects. For more details of these not yet standardized procedures see Choy and Boatwright (2012) and Di Giacomo and Bormann (2011).

In contrast to measuring M_0 , for which a sufficient condition is that the spectral plateau amplitude u_0 is measured at $f \ll fc$, a reliable estimation of Es requires to integrate the seismic moment rate for about one decade in frequency towards both sides of fc . This requires to take much more higher frequencies into account than in M_0 determination. Since higher frequencies are much more affected by heterogeneities of the real source process and Earth medium and also more difficult to treat in the model calculations, Es and thus M_e estimates are generally less accurate than M_0 and M_w estimates. But in contrast to M_w , M_e is a dynamic measure of earthquake size, which should better be called earthquakes strength. It is controlled by differences in stress drop and the related Es/M_0 ratio, which are associated with differences in rupture velocity and duration (see Fig. 5). Accordingly, the M_e formula can also be written (Bormann and Di Giacomo 2011)

$$\begin{aligned} M_e &= M_w + [\log(\Delta\sigma/2\mu) + 4.7]/1.5 \\ &= M_w + [\log(Es/M_0) + 4.7]/1.5. \end{aligned} \quad (5)$$

Because of the variability of the term in brackets M_e and M_w may differ by several tenths m.u., in the extreme by even more than one m.u. Therefore, M_w and M_e are very important complementary magnitudes reflecting the difference in static and dynamic properties of the earthquake source. M_w alone, being independent on the corner frequency and thus the relative amount

Earthquake Magnitude Estimation,

Fig. 5 Velocity broadband records of three earthquakes with similar M_w but exceptionally different rupture durations and large differences in $m_B(\text{BB})$ values. The gray shaded area marks, as in Fig. 14, the envelope of high-frequency radiation for estimating the rupture duration (Copy of Fig. 3 in Bormann and Saul 2008, SRL © Seismological Society of America)

of high-frequency energy, is not the most suitable magnitude for assessing the actual seismic hazard associated with an earthquake, be it of its damage potential due to strong shaking or of its potential to generate a tsunami. Here even the relationship between the classical long-period M_S and m_b , respectively M_L , may already be more telling than M_w alone. For example, M_L is measured at frequencies of particular interest to earthquake engineers, because they are in the preferred vulnerability range of man-made structures.

Recent publications have shown that considering the difference between M_w and M_e is particularly suitable for a more realistic near real-time assessment of potential effects (e.g., Choy and Kirby 2004; Di Giacomo et al. 2010a; Bormann and Di Giacomo 2011). Generally holds, suitable seismotectonic setting, site conditions, and exposure of vulnerable objects provided, that $M_e \ll M_w$ may be indicative for high tsunamigenic potential and related risk, and vice versa, $M_e \gg M_w$ for high shaking damage potential. But the differential magnitude $M = M_w - M_e$ is also of interest for basic research, e.g., the classification of seismotectonic regions with

respect to their fault maturity and thus capability (Choy and Boatwright 2012). For more details on the relationship between M_w and M_e see also Choy and Boatwright (2012), Bormann and Di Giacomo (2011) and Bormann et al. (2013).

Similarly important it is to consider the difference between M_w and $m_B(\text{BB})$ because the latter correlates very closely with M_e (Fig. 6). Figure 5 shows that for a given M_w $m_B(\text{BB})$ is inverse proportional to the rupture duration and thus proportional with rupture velocity and the related stress drop, as does the ratio E_S/M_0 and thus M_e .

The orthogonal relationship and standard deviation between M_e and $m_B(\text{BB})$ is:

$$M_e = 1.27 \, m_B(\text{BB}) - 1.98 \pm 0.11. \quad (6)$$

From the classical magnitudes, M_S relates best to M_w , also due to the fact that the M_w relationship has been derived via the log E_S - M equation (20) in section Relationships Between Magnitude Scales and Released Seismic Energy E_S . However, Bormann et al. (2009) showed that the new IASPEI broadband standard $M_S(\text{BB})$ correlates on average better with M_w than $M_S(20)$, reducing

to half the systematic underestimation of M_w by $M_S(20)$ for magnitudes less than about 6.7 (Fig. 7). The $M_S(20)$ bias had already been predicted theoretically by Kanamori and Anderson (1975) and empirically confirmed by Ekström and Dziewonski (1988).

Magnitude Scales and the New IASPEI Measurement Standards

Local Magnitude M_L

The definition of M_L and the traditional procedure of its determination have already been

outlined in the introduction. For crustal earthquakes in regions with attenuative properties similar to those of Southern California the formula for the new IASPEI standard M_L (= M_L when written in the IASPEI Seismic Format ISF for magnitude data), has the following form:

$$M_L = \log_{10} A_{\max} + 1.11 \log_{10} R + 0.00189 * R - 2.09 \quad (7)$$

where $A_{\max}$ = maximum trace amplitude in nm that is measured on the output from a horizontal-component instrument that is filtered so that the response of the seismograph/filter system replicates that of a WA standard seismograph (see ► [Seismic Instrument Response, Correction for](#)) but with a static magnification of 1 (as in Fig. 8), and R = hypocentral distance (see ► [Earthquake Location](#)) in km, typically less than 1,000 km. The constant term in (1), -2.09 , is based on an experimentally determined average static magnification of the WA seismograph of 2080 (Uhrhammer and Collins 1990) and aims at making reported M_L amplitude data unaffected by its uncertainty (Bormann and Dewey 2012).

The calibration function (7) is an expansion of the Hutton and Boore (1987) formula for Southern California (see Fig. 9). For crustal earthquakes in regions with different attenuative properties and for measuring magnitudes with vertical-component seismographs, the standard equation is of the form:

$$M_L = \log_{10}(A_{\max}) + C(R) + D \quad (8)$$

where $A_{\max}$ and R are defined as in Eq. 7, except that A may be measured from a vertical-component instrument, and where $C(R)$ and D have been calibrated to adjust for the different regional attenuation and for any systematic differences between amplitudes measured on vertical instead of horizontal components. Often a station correction term S is still added in those magnitude calibration relationships in order to correct for abnormal (non-average) geologic and/or topographic condition on the recording site.

Earthquake Magnitude Estimation, Fig. 8 Displacement amplitude-frequency responses of the classical seismographs: Wood-Anderson (WA), WWSSN-SP and WWSSN-LP (short-period and long-period standard seismographs of the former US World-Wide Standard Seismograph Network), normalized to a static magnification of 1 at 0.04 Hz for the WWSSN-LP, at 1 Hz for WWSSN-SP and at 4 Hz for the WA seismograph (Copy of Fig. 1 in Bormann and Dewey 2012 © IASPEI)

Figure 9 illustrates how much the M_L calibration functions may differ for regions of different geological age, structure, heat flow and thus attenuation conditions. This highlights the need for scaling other regional M_L formulas to formula (7) so as to assure globally compatible M_L values. Note in this figure the calibration curves published by Wahlström and Strauch (1984). They include besides the curve for calibrating amplitude measurements at 1 Hz also curves for measurements at 2 and 4 Hz. They illustrate the strong influence of frequency-dependent attenuation which has not been considered in Richter's original and all other later developed M_L formulas although $A_{\max}$ may also occur at frequencies in this range. By not accounting for frequency dependence increases the scatter of derived M_L values.

Besides M_L scales that measure $A_{\max}$, typically of relatively weak motion, also M_L^{SM} scales have been developed that measure peak ground accelerations on *strong-motion records*. Also the duration d of the event record (see Fig. 1) can be used for estimating magnitude. But any such

Earthquake Magnitude Estimation, Fig. 9 Calibration functions $\sigma(\Delta) = -\log A_0$ for M_L determination in different regions. Some of them extend well beyond the 600 km distance plotted. But even at much shorter distance, such as the 320 km chosen here for demonstration, the

difference between M_L according to the Richter scale and other regional scales may already amount to 0.5 m.u. for equal measurement amplitudes $A_{\max}$ (Copy of Fig. 3.3 in Bormann et al. 2013 © IASPEI)

alternative local M_d scale has to be developed individually for different regions or seismic networks because of regionally variable attenuation, scattering, signal-to-noise, and other conditions. Moreover, for assuring the compatibility of their values with M_L , these scales have to be calibrated with amplitude-based M_L .

Teleseismic Magnitude Scales

Surface-Wave Magnitudes

IASPEI (2013) recommends to determine for shallow earthquakes with source depth $h < 50\text{--}60$ km two surface-wave magnitude standards, namely

- (a) A purely teleseismic magnitude in the distance range $20^\circ \leq \Delta \leq 160^\circ$ ($1^\circ = 111.12$ km) termed $M_S(20)$, or, in the ISF format

$$M_{S_20} = \log_{10}(A/T) + 1.66 \log_{10} \Delta + 0.3 \quad (9)$$

where A = vertical-component ground displacement in nm measured from the maximum surface-wave trace-amplitude having a period between 18 s and 22 s on a waveform filtered so as to replicate the record of the WWSSN-LP seismograph (Fig. 8), and

- (b) A broadband (BB) surface-wave magnitude that is measured in the wider regional to teleseismic distance range of $2^\circ \leq \Delta \leq 160^\circ$, termed $M_S(BB)$, or in the ISF format:

$$M_{S_BB} = \log_{10}(V_{\max}/2\pi) + 1.66 \log_{10} \Delta + 0.3 \quad (10)$$

where $V_{\max}$ = ground velocity in nm/s associated with the maximum trace-amplitude in the surface-wave train as recorded on a vertical-component seismogram that is proportional to velocity, and where the period T is in the range between $3 \text{ s} < T < 60 \text{ s}$.

Equations 9 and 10 are based on the M_S calibration relationship proposed by Vaněk et al. (1962) which is IASPEI recommended standard since 1967. But in the new standards it is applied to vertical motion measurements only and in Eq. 10 the $\log_{10}(V_{\max}/2\pi)$ term replaces the $\log_{10}(A/T)_{\max}$ term of the original. Equation 9 is since the 1970s exclusive M_S standard at the US National Earthquake Information Center (NEIC). However, most surface-wave amplitude maxima occur at periods outside of the period range accepted by $M_S(20)$ (Fig. 10; Vaněk et al. 1962; Bormann et al. 2009). Moreover, using the standard M_S calibration function exclusively for amplitude readings around 20 s introduces in some ranges systematic distance and magnitude-dependent biases of up to 0.5 m.u. Therefore, the determination of $M_S(\text{BB})$, most easily measured on nowadays widely available velocity BB records, is preferable.

Besides these standards there exist still other surface-wave magnitudes. Bonner et al. (2006) proposed a largely theory-based version, applying multi-bandpass filtering and frequency-dependent attenuation corrections. Yet, according to Bormann et al. (2009), their sophisticated $M_S(V_{\max})$ procedure yields practically the same results as the much simpler $M_S(\text{BB})$ which can be performed easily by any station analyst (Bormann et al. 2009). Another one uses very long-period surface-wave amplitudes with periods between 60 and 400 s, which penetrate into the earth mantle. This “mantle magnitude” M_m (Okal and Talandier 1989) is not prone by saturation and thus suitable also for tsunami early warning (Weinstein and Okal 2005). The Comprehensive Test-Ban Treaty Organization (CTBTO) applies another 20 s surface-wave calibration formula by Rezapour and Pearce (1998) which avoids the systematic distance-dependent biases of $M_S(20)$.

Body-Wave Magnitudes

Gutenberg (1945a, b) proposed teleseismic magnitude scales for body waves of type P, PP, and S. This allowed him to assess also the seismic energy released by deep earthquakes. Calibration functions $Q(\Delta, h)$ for amplitude readings on both

vertical and horizontal component records of P and PP waves, respectively on horizontal component S-wave records, were published by Gutenberg and Richter (1956) and the respective magnitudes were termed m_B . Figure 11 shows the Q -values for vertical component P waves as a function of Δ and h . Regrettably, it is the only one still in wide routine use, although S-wave amplitude, period and magnitude data would be of great complementary value for improved studies of the physical properties of Earth matter and seismic source mechanisms. And PP waves would allow to measure body-wave magnitude still with good signal-to-noise ratio in the “core-shadow” range beyond 100° distance where due to the influence of the liquid outer Earth core direct P and S waves are no longer recorded or only recorded as weak long-period diffracted waves.

When elaborating these scales, Gutenberg realized that body-wave magnitudes measured at different sites are compatible and stable only when measuring the ratio $(A/T)_{\max}$ in a wide period range instead of just measuring $A_{\max}$ or measuring $A_{\max}$ in a narrow frequency range. Measuring $(A/T)_{\max}$ corresponds to measuring $V_{\max}/2\pi$ in the IASPEI standard formula (10) for $M_S(\text{BB})$. Accordingly, his general body-wave magnitude formula reads, with A measured in μm :

$$m_B = \log_{10}(A/T)_{\max} + Q(\Delta, h). \quad (11)$$

Gutenberg derived the Q -functions by analyzing mostly medium- to long-period body-wave amplitudes in the range $2 \text{ s} < T < 30 \text{ s}$. Therefore he did not account for frequency-dependent attenuation, which becomes significant for P-waves with $T < 4 \text{ s}$ (see Sect. 2.5.4.2 in Bormann et al. 2013). Further, Gutenberg measured always $(A/T)_{\max}$ within the whole P-wave train and not only within a fixed limited time window after the P-wave onset. Yet, this was not considered when introducing, in conjunction with the deployment of the WWSSN in the 1960s, another short-period P-wave magnitude scale m_b . However, as compared to m_B , m_b had the clear advantage of enabling teleseismic

Earthquake Magnitude Estimation, Fig. 10 Three-component distance-period plots for $(A/T)_{\max}$ surface wave readings retrieved at the ISC from printed station/network bulletins for earthquakes that occurred before

1971 and therefore were not dominated by the more narrow-band WWSSN records (Copy of Fig. 3.35 in Bormann et al. 2013 © IASPEI)

Earthquake Magnitude Estimation, Fig. 11 Calibration values $Q(\Delta, h)$ for vertical (Z) component P-wave amplitudes as a function of epicentral distance Δ and source depth h . They are used for the calculation of the

two body-wave magnitudes m_b and m_B (Figure redrawn from Gutenberg and Richter (1956). For standard tabulated QPZ values see Table 2 in Bormann and Dewey (2012))

magnitudes measured down to about magnitude 4, and thus to classify the many more small earthquakes now being recordable with the much more sensitive instruments now available than those available at Gutenberg’s time.

But m_b still uses the same formula and $Q(\Delta, h)$ values for medium-period P waves as in (5) and measures $A_{\max}$ only on narrow-band WWSSN-SP (see Fig. 3) or similarly filtered short-period records at periods <3 s (mostly around 1 s). This practice became standard in all western countries, which discontinued to measure m_B , although m_b heavily underestimates the body-wave magnitude for large earthquakes (see Introduction). This is mainly due to the earlier-cited phenomenon of spectral saturation (see section Relationships Between Magnitude Scales and Released Seismic Energy E_s). This effect of underestimating earthquake size has been further aggravated by the often too short time window for measuring $A_{\max}$ after the P-wave onset. In early years of the WWSSN, this window had been fixed

to the first few cycles within about 6 s after the onset of P. It is still used by several agencies such as the International Data Center (IDC) of the CTBTO or the China Earthquake Network Center (CENC), despite the 1978 IASPEI recommendation that for small and medium size earthquakes $A_{\max}$ should be measured within 20 s after the first onset and that this time window be extended up to 60 s for very large earthquakes. Even a simple relationship between rupture duration and magnitude, such as Eq. 1, makes it obvious that m_b measurements within the very first few seconds necessarily tend on average to underestimate the size of events with $M > 6$, because it becomes increasingly unlikely that they are based on the true $A_{\max}$ radiated by the considered rupture. But also the extension of the measurement time window up to 60 s will not always be sufficient for really great earthquakes that rupture for several minutes. The new standards for body-wave magnitudes, measuring always the true $A_{\max}$ within the whole P-wave train, avoid this measurement

Earthquake Magnitude Estimation, Fig. 12 Difference between standard $m_B(\text{BB})$ and m_b . Plotted are the vertical-component P-wave records of an M_w 8.4 Peru earthquake at station MTE, Portugal ($\Delta = 83.4^\circ$). On the top trace, m_b is determined by measuring $A_{\max}$ and the related period T from the WWSSN short-period recording that has been simulated from the original BB velocity trace on the bottom. On the second trace the time derivative of the

top trace is depicted in order to make the measurement units directly compatible with the bottom trace. On the bottom trace $V_{\max}$ is measured, yielding $m_B(\text{BB}) = 8.2$, in contrast to standard $m_b = 7.0$. If, however, $A_{\max}$ is measured on the top trace within the first 5 s then one would get $m_b = 6.4$ only (Copy of Fig. 1 in Bormann and Saul 2008, SRL © Seismological Society of America)

time-window component of saturation. For the great Mw 9.3 Sumatra-Andaman earthquake of December 26, 2004, the smallest reported m_b was 5.7, the new standard m_b yielded 7.5. But what also standard m_b cannot avoid is the spectral component of saturation which is so obvious when comparing the lower two traces and related velocity amplitudes of $8 \mu\text{m/s}$ and $123 \mu\text{m/s}$, respectively, in Fig. 12. This spectral component of saturation is strongly reduced by $m_B(\text{BB})$ that is measured for large earthquakes at significantly larger periods (Figs. 3 and 12).

Taking the results of several related studies into account, IASPEI (2005; latest version 2013) recommends two complementary body-wave magnitude standards, namely, a short-period version m_b , or mb in the ISF format:

$$mb = \log_{10}(A/T) + Q(\Delta, h) - 3.0 \quad (12)$$

where A = P-wave ground amplitude in nm, calculated from the maximum trace-amplitude in the entire P-phase train (time spanned by P, the depth phases pP, sP, and possibly also the core

Earthquake Magnitude Estimation,

Fig. 13 Comparison between the original Gutenberg and Richter (1956) QPZ values for vertical component P waves from earthquakes at depth <70 km with preliminary data based on broadband velocity P-wave amplitude measurements by Saul and Bormann (2007). The Saul and Bormann curve is associated with curves representing $\pm$ the standard error, which is also plotted separately at the top of the figure (Copy of Fig. 16 in Bormann and Dewey 2012 © IASPEI)

reflection PcP and their codas, and ending preferably before PP); T = period of A in seconds with $T < 3$ s, Δ = epicentral distance in the range $20^\circ \leq \Delta \leq 100^\circ$ and h = focal depth between $0 \text{ km} < h \leq 700 \text{ km}$. Both T and A are measured on output from a vertical-component instrument/filter that simulates a WWSSN-SP seismograph (Fig. 8). Although the early saturation of mb has been reduced by this new definition up to about one magnitude unit, the short-period body-wave magnitude still needs to be complemented – at least for $mb > 5.5$ – by a broadband $m_B(\text{BB})$, or mB_BB in ISF format:

$$mB_BB = \log_{10}(V_{\max}/2\pi) + Q(\Delta, h) - 3.0. \quad (13)$$

with $V_{\max}$ = ground velocity in nm/s associated with the maximum trace-amplitude in the entire P-phase train (as for standard m_b), recorded on a vertical-component seismogram that is proportional to velocity at least in the period range $0.2 \text{ s} < T < 30 \text{ s}$; $Q(\Delta, h)$. The ranges for Δ and h are the same as for standard m_b . As seen from Fig. 11, Gutenberg and Richter (1956) had given calibration values down to $\Delta = 5^\circ$. Since $m_B(\text{BB})$ has proven to be a very suitable earliest available proxy estimator for both seismic moment and

energy magnitude, M_w and M_e (see section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#); Bormann and Saul 2008; 2009a; Bormann et al. 2013), it would be very beneficial to measure $m_B(\text{BB})$ already from distances 5° onwards, e.g., in tsunami early warning schemes. However, the original Gutenberg and Richter QPZ values are not reliable enough in the regional range. A first version of an improved regional calibration relationship has been developed for $m_B(\text{BB})$ (Fig. 13) and is used already operationally in the German-Indonesian Tsunami Early Warning System (GITEWS).

Besides these two body-wave standards there exist several other broadband P-wave magnitudes by various authors which aim at fast estimates of a non-saturating moment magnitude M_w (see Sects. 3.2.7 and 3.2.8 in Bormann et al. 2013). The most successful ones account in different ways also for the rupture duration. One example is given for the great Mw 9.3 Sumatra-Andaman earthquake of 2004 in Fig. 14, analyzed by the fully automated cumulative body-wave magnitude mBc procedure (Bormann and Saul 2009b). Its principle was proposed by Bormann and Khalturin (1975). The justification for the new scale was that Gutenberg and Richter (1956) assumed for

Earthquake Magnitude Estimation, Fig. 14 Plot that illustrates the measurement of the cumulative body-wave magnitude m_{Bc} for the great Sumatra-Andaman earthquake with a rupture duration of about 540 s. The strong P-wave radiation continues well into the time after the first theoretical PP onset. The rupture duration D is estimated from the envelope of high-frequency radiation on a 1–4 Hz filtered record channel (gray shaded area). D is assumed to correspond approximately to the time window from the first P-wave onset until the envelop amplitude

drop to 40 % of its maximum values, i.e., some 16 % of the released high-frequency seismic energy. Blue columns give the m_B values related to subsequent new energy arrivals radiated from sub-rupture events; the red curve shows the development of m_{Bc} with time by summing up significant sub-event amplitudes until saturation is achieved towards the end of the rupture (Cut-out of Fig. 1 from Bormann and Saul 2009b, SRL © granted by Seismological Society of America)

the m_B determination and the relationship derived between m_B and E_S that the P-wave train has on average a simple symmetric waveform radiated by a “point source” (see section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#)). They explicitly stated that they were not sure whether this still holds for very great earthquakes for which they had not enough data. But great earthquakes rupture in a more or less complicated sequence of sub-events. The velocity amplitudes for m_B should therefore be measured individually for major sub-events and summed up toward the end of the rupture process for getting a cumulative m_B estimate, termed m_{Bc} .

Earthquake Early Warning Magnitudes

In recent years great attention has been paid to the development of [Earthquake Early Warning Systems](#) (EEWS). They allow – besides very quick event location – near real-time magnitude estimates from the very first few seconds of acceleration, velocity or displacement records at stations close to the earthquake source. Based on such data, rapid public alarms may be issued

and/or automatically triggered risk mitigation actions taken between the detection of a strong earthquake at the close-up stations and the arrival of strong ground motion at locations slightly further away. EEWS aim at minimizing the area of so-called “blind zones” which are left without advanced warning before the arrival of the S waves which have usually the largest strong-motion amplitudes. This requires very dense and robust seismic sensor networks within a few tens of km from potentially strong earthquake sources. Such dense networks are at present already available in several regions, e.g., in California, Japan, Taiwan, Turkey (Istanbul), and Italy (see [Source Characterization for Earthquake Early Warning](#)).

The principles of rapid magnitude estimates are rather different from those mentioned above and largely based on much debated concepts such as the hypothesis of the deterministic nature of earthquake rupturing. For example, Olson and Allen (2005) claim to be able to estimate, from the maximum period of the first arriving P waves within the first 4 s, the size of earthquakes up to magnitude 8 with an average absolute deviation

of 0.54 m.u. using many low-pass filtered velocity records within 100 km epicentral distance. However, Rydelek and Horiuchi (2006) could not confirm that such a dominant frequency scaling with magnitude exists. Also extensive experiments run at the Taiwan EEWS, aimed at reducing the reporting time from 25 s down to about 8 s by using only the records of the first 8 stations within less than 21 km epicentral distance (Wu and Kanamori 2005) came to sobering results. Estimating the magnitude via the magnitude dependence of the average period τ_c of the P-wave, as well as the peak displacement amplitudes (if > 0.1 cm) within the first 3 s of the low-pass filtered displacement signal after the P-wave onset the authors concluded:

*“... For EWS applications, if $\tau_c < 1$ sec, the event has already ended or is not likely to grow beyond $M > 6$. If $\tau_c > 1$ sec, it is likely to grow, but how large it will eventually become, cannot be determined. In this sense, the method provides a **threshold warning**.” And: “... If $\tau_c > 1$ sec, the event is potentially damaging. If it is larger than 2 sec, the event is almost certainly damaging. Combining this information with other data, such as the initial velocity and displacement amplitudes, would allow the damage potential of the event to be assessed more accurately”.*

More can indeed not be said within the first 3–4 s of a record, especially not for strong and great earthquakes. This fully agrees with relationship (8) between average rupture duration τ_{rup} and M . For earthquakes with $M \leq 6$ and $\tau_{rup} \leq 6$ s it can indeed be expected that, within a measurement time window of 3–4 s, the maximum amplitude and related period of the P-wave train can be measured and are representative for the earthquake magnitude but not for magnitudes much larger than 6 and rupture durations of several 10 to several 100 s. Then, inevitably, as for the current near real-time magnitude estimates in tsunami early warning systems (TEWS), much larger measurement time windows up to about one minute (e.g., Lomax and Michelini 2012) or even longer for mega-earthquakes may be required. This general conclusion is fully confirmed by results from Southern California where the magnitude has been estimated by measuring the P-wave amplitudes

within the first three seconds of the record. These Pd magnitudes agreed with catalog magnitudes with a standard deviation of ± 0.18 m.u. for events with magnitudes < 6.5 but saturated for larger ones and could not be used to estimate magnitudes ≥ 6.7 (Wu and Zhao 2006). For a summary of related studies and information on several representative EEWS, their magnitude concepts and performance see Sect. 3.2.6.5 in Bormann et al. (2013).

Relationships Between Magnitude Scales and Released Seismic Energy E_s

The local and teleseismic magnitudes discussed above are not identical (see Fig. 15). They only agree at some specific magnitude values and differ at others. Moreover, all classical magnitude scales show for large or very great earthquakes more or less pronounced underestimation of earthquake size as compared to a non-saturating purely displacement amplitude-based magnitude such as the moment magnitude M_w . But underestimation of the moment related earthquake size may also occur if magnitudes that are based on the measurement of A/T , such as m_b and $M_S(20)$, are measured outside of the period range of maximum seismic energy release. This is obvious from the nonlinear relationships of these classical magnitudes with M_w (Fig. 15). The reasons have been explained in section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#). This notwithstanding, most classical relationships between different types of magnitudes have been published only as simple linear standard regression relationships that maybe rather biased by noisy data because they assume that only one of the compared magnitudes is afflicted with measurement errors. Only recently has it become common to calculate general orthogonal linear and even nonlinear regression relationships. For a summary on this issue see Sect. 3.2.9 in Bormann et al. (2013). Only the most important classical and a few recently derived relationships of interest are presented here.

Earthquake Magnitude Estimation, Fig. 15 Average relationships of different common types of magnitude scales with respect to the non-saturating moment magnitude M_w . M_{JMA} is determined by the Japanese

Meteorological Agency (Modified Fig. 1 of Utsu (2002). Reproduction of Fig. 4 in Bormann and Saul 2009a © Springer; with kind permission from Springer Science + Business Media)

According to Gutenberg and Richter (1956)

$$m_B = 0.63 M_S + 2.5. \quad (14)$$

This relationship has been very well reproduced between the new standard magnitudes $m_B(BB)$ and $M_S(BB)$ (Bormann et al. 2009) in an even wider magnitude range than that investigated by Gutenberg and Richter (1956). But Eq. 14 differs strongly from the relationship between short-period m_b and $M_S(20)$ (Gordon 1971):

$$m_b = 0.47 M_S(20) + 2.79. \quad (15)$$

The relationship between the two new IASPEI standard magnitudes for body waves and surface-waves, respectively, are depicted in Fig. 16 and their formulas are given in the figure caption.

Regression relationships between magnitudes are frequently used to convert data of one type of magnitude into another one. For example, Gutenberg used – in an effort to unify different magnitude estimates per event into a single number – relationship (9) for converting M_S data into m_B which he considered superior to M_S , better physically defined, applicable also to deep earthquakes and less affected by uncertainties in estimates of source depth. Nowadays it

has become common to convert classical magnitudes via empirical conversion relationships into M_w which is often considered as the physically best defined and with smallest measurement errors of about $\leq \pm 0.1$ m.u. afflicted magnitude. Such a unification of magnitude estimates is desirable especially for *seismic hazard assessment* (see ► [Probabilistic Seismic Hazard Models](#)). The latter strongly depends on the parameters **a** and **b** derived from a Gutenberg and Richter (1954) relationship $\log N = \mathbf{a} + \mathbf{b}M$ between magnitude M and the number N of earthquakes that occur on average in a given period of time, usually normalized as of per year (see ► [Earthquake Recurrence](#)). However, reliable instrumentally measured M_w data as in the Global Centroid Moment Tensor catalog (<http://www.globalcmt.org>) are available and complete only since 1975 and for $M_w \geq 5.5$. This time span is too short for reliable long-term seismic hazard assessment. To include earlier events into the $\log N - M_w$ analysis one has to try the conversion of classical M_S , or of the most frequently determined m_b , into M_w . The rather good correlation between M_S and M_w for larger earthquakes is no wonder because the M_w formula (3) has been scaled by Kanamori (1977) and Hanks and Kanamori (1979) via the $\log E_S - M_S$ relationship (20) to M_S . The most recent, both linear and

Earthquake Magnitude Estimation, Fig. 16 Relationships between the two new IASPEI standard body-wave magnitudes (*left panel*) and surface-wave magnitudes $M_s(20)$ and $M_s(BB)$ (*right panel*). The orthogonal

regression relations are $m_b = 0.91 m_B(BB) + 0.20$ and $M_s(20) = 1.10 M_s(BB) - 0.75$ (Cut-out of Fig. 11 in Bormann et al. 2009, BSSA © Seismological Society of America)

Earthquake Magnitude Estimation, Fig. 17 Training data sets for deriving the ISC-GEM $M_s - M_w$ (*left*) and $m_b - M_w$ (*right*) general orthogonal linear (*green*) and exponential (*blue*) conversion relationships. The dashed

black polygon line represents the median values for separate magnitude bins (Figure modified and compiled according to Figs. 14 and 17 of Di Giacomo et al. 2014 © PEPI)

nonlinear regression relationships of M_s and m_b with M_w have been calculated at the International Seismological Centre (ISC) in the framework of *The Global Earthquake Model (GEM)* project for

deriving a Global Instrumental Earthquake Catalogue (1900–2009) (Di Giacomo et al. 2014). Figure 17 shows these respective data together with the orthogonal linear and standard

exponential regression lines. The related equations for $M_w - M_S$ are given in (16–18),

One realizes, when compared with $M_S - M_w$, the much larger data scatter and thus much larger uncertainty of estimating M_w via m_b . Therefore, the latter conversion should be avoided whenever M_S data are available. But even such proxy M_w estimates via M_S are afflicted with at least twice the error of direct high quality instrumental M_w estimates. For most practical applications, however, it may be still acceptable to use for M_S conversion into M_w instead of the more accurate exponential relationship

$$M_w = e^{(-0.222+0.233 \times M_S)} + 2.863 \quad (16)$$

the two orthogonal linear relationships

$$M_w = 0.67M_S + 2.13 \quad \text{for } M_S \leq 6.47 \quad (17)$$

and

$$M_w = 1.10M_S - 0.67 \quad \text{for } M_S > 6.47 \quad (18)$$

However, because of the incompleteness of GCMT data for $M_w < 5.5$ these relationships should not be applied for converting $M_S < 5$ into M_w . With respect to deviations between standard and orthogonal linear and exponential conversion relationships, especially for m_b and M_S into M_w and their extension into lower magnitude ranges on the basis of regional M_w catalogs, see Lolli et al. (2013) and Sect. 3.2.9.1 in Bormann et al. (2013) with the references given therein.

Gutenberg and Richter (1956) published a semiempirical relationship between the classical m_B and released seismic energy Es

$$\log Es = 2.4m_B - 1.2 \quad (\text{with } Es \text{ in units of Joule}), \quad (19)$$

because only m_B measured the maximum ground motion velocity, proportional to $(A/T)_{\max}$, in a one decade wide period range. However, since in western countries m_B was no longer measured after the 1960s, a proposal by Richter (1958) to insert (14) into (19) was followed and this gave

$$\log Es = 1.5 M_S + 4.8 \quad (20)$$

with Es in units of Joule and M_S meaning an $M_S(20)$. However, 20 s displacement amplitudes are not very representative for the radiated seismic energy, especially not for smaller earthquakes that radiate dominantly higher-frequency energy.

Nevertheless, Eq. 20 has become since the 1960s the most widely used rough estimator for seismic energy release via magnitude and it was instrumental for deriving the non-saturating moment magnitude scale M_w (see section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#)). Moreover, it has been modified by Choy and Boatwright (1995) when correlating direct Es measurements with NEIC $M_S(20)$ data and assuming the same slope as in (20) [see relationship (22)].

Another relationship has been derived by Kanamori et al. (1993) between M_L and Es for Southern California, valid in the range $1.5 < M_L < 6.0$:

$$\log Es = 1.96 M_L + 2.05. \quad (21)$$

Formula (21) is very close to a theoretically expected general relationship $\log Es \propto 2.0 M$ because Es should be proportional to squared ground motion velocity amplitudes. This is obviously well approximated by high-frequency $A_{\max}$ but not ideally by more long-period P- and surface waves [see formulas (19) and (20)]. Differences in the spreading terms and attenuation of body- and surface waves may also influence the slope of empirically determined regression relationships. Anyway, all these relationships allow only rough estimates of the released seismic wave energy, probably within an order of magnitude.

The uncertainty of Es estimates may nowadays be reduced, down to a factor of about 3–5, by integrating squared velocity broadband records with good signal-to-noise ratio in the teleseismic range (see section [Earthquake Rupture, Radiated Seismic Spectrum, Seismic Moment, Energy and Related Magnitudes](#);

Earthquake Magnitude Estimation, Fig. 18 Orthogonal (OR) and standard regressions (SR and its inverse ISR) of $\log E_s$ data for different earthquake source mechanisms, determined by the procedure of Di Giacomo et al. (2008 and 2010b) plotted over m_B (BB) data (left-hand panel),

respectively M_s (20) data of the NEIC (right-hand panel). GR Gutenberg and Richter (1956) relationship, C&B Choy and Boatwright (1995) relationship (Compiled from Figs. 3.85 and 3.86 in Bormann et al. 2013 © IASPEI)

Choy and Boatwright 2012; Di Giacomo and Bormann 2011). Regressing such modern energy measurements with different magnitudes it could be shown that indeed standard m_B (BB) correlates, as expected by Gutenberg, much better with $\log E_s$ than M_s (20). This allows rather reliable energy estimates via m_B (BB). But the classical relationship (19) could not be reproduced well with modern E_s data. On the other hand, although with double data scatter than with m_B (BB), the Choy and Boatwright (1995) relationship

$$\log E_s = 1.5M_s(20) + 4.4 \quad (22)$$

could be well reproduced by orthogonal regression (Fig. 18).

Summary

Magnitudes are one of the most important earthquake parameter data. When properly determined and applied they may allow quick estimates of the tectonic effect of actual earthquakes in terms of rupture area and slip and/or of the released seismic energy in different frequency ranges and thus

of the potential strength of earthquake shaking to be expected. Moreover, in the long run, they also permit to quantify the seismic activity and its variability in space and time, which is a prerequisite for seismic hazard assessment. This necessitates, however, the compatibility and long-term stability of magnitude estimates of the various types on a global scale. The essay shows that just this is often not the case. Procedural differences in magnitude determination, even of supposedly the same type, may occasionally reach even more than one magnitude unit, especially for the most seldom but therefore most important and devastating great earthquakes. In view of the logarithmic scaling of magnitude values this may correspond to wrong estimates of released seismic energy by a factor of 1,000 times or even more. This highlights the urgency of international standards in magnitude measurements. For the most important classical magnitudes such standards have recently been agreed upon by IASPEI and recommended for global operational application. Their principles and underlying physical considerations, advantages and limitations are outlined in the essay, also in relation to other types of magnitudes such as modern M_w and M_e

as well as of their near real-time proxy estimates in the earthquake and tsunami early warning context. Also given are some of the most important correlation relationships between different types of magnitudes but with cautioning remarks on their often uncritical application in efforts to homogenize earthquake catalogs in terms of magnitude. In fact, there is no single type of magnitude that can sufficiently well describe both the geometric size and kinematic-dynamic effects of earthquakes. What is needed is a deeper understanding and conscious use of the beneficial complementarity of different magnitude scales. For comprehensive information on this complex issue reference is made to the online IASPEI New Manual of Seismological Observatory Practice (NMSOP-2; <http://nmsop.gfz-potsdam.de>).

Introduction

Tsunamis are generated in the ocean by rapidly displacing the entire water column over a significant area. The potential energy resulting from this disturbance is balanced with the kinetic energy of the waves during propagation. Only a handful of submarine geologic phenomena can generate tsunamis: large-magnitude earthquakes, large landslides, and volcanic processes. Asteroid and subaerial landslide impacts can generate tsunami waves from above the water. Earthquakes are by far the most common generator of tsunamis. Generally, earthquakes greater than magnitude (M) 6.5–7 can generate tsunamis if they occur beneath an ocean and if they result in predominantly vertical displacement. One of the greatest uncertainties in both deterministic and probabilistic hazard assessments of tsunamis is computing seafloor deformation for earthquakes

of a given magnitude. This entry reviews past methodologies and current developments of seismogenic tsunami generation models.

Subduction zones are the tectonic plate boundaries where most seismogenic tsunamis are sourced. Three factors combine to explain this observation: (1) most subduction zones occur beneath oceans, (2) most of the world's largest earthquakes occur along subduction zones, (3) the dominant mechanism of subduction zone earthquakes is thrusting, resulting in significant vertical displacement of the seafloor. Normal-faulting earthquakes in the outer rise and outer trench slope of subduction zones and thrust faulting in the back arc can also generate tsunamis. Other tectonic environments where seismogenic tsunamis can occur are oceanic convergence boundaries as distinguished from subduction zones by Bird (2003) and local, submarine dip-slip fault zones in intraplate settings.

To simulate the tsunami generation process, elastic deformation models are needed to determine the magnitude and pattern of seafloor displacement from earthquake source parameters. To calculate the initial tsunami amplitude distribution on the ocean surface, a $1/\cosh(kh)$ low-pass filter is applied to the seafloor displacement field, where k is the wave number and h is the water depth (Kajiura 1963). This filter primarily has an effect for small earthquakes and surface-rupturing earthquakes that generate a scarp or short-wavelength displacement. Otherwise, the initial wave field of a tsunami is almost identical to the vertical seafloor displacement field. Horizontal displacements also contribute to tsunami generation in regions of steep bathymetry (Tanioka and Satake 1996). Although the rupture process of large subduction zone earthquakes is extremely complex, simple mechanical models have traditionally been used to simulate seafloor displacement and tsunami generation up until recently. These models assume that the earthquake occurs instantaneously relative to the phase speed of the tsunami, often referred to as static or coseismic models.

A significant advancement in simulating tsunami generation is the use of dynamic rupture models. These models simulate the rupture process

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation,

E

along the fault itself, as well as dynamic deformation of the surrounding rocks, including dynamic stress transfer from seismic waves as well as the final static seafloor displacement. The time-varying displacement of the seafloor is extracted from these models and is used to force the tsunami in the source region. The time-varying aspect of the seafloor motion is not likely to be a large factor in tsunami generation, but as will be shown below, the final earthquake size, slip distribution, and rupture path do depend critically on the spatiotemporal details of the rupture process.

First, the most common class of static mechanical models based on dislocation theory is discussed. Static crack models are then described that have several advantages over traditional dislocation models. General methods for incorporating heterogeneous slip, particularly from stochastic slip models, are next discussed. Finally, recent advances in using dynamic rupture models for tsunami generation are reviewed. Because details among the different tsunami generation models are smoothed out in the far field, the focus in this entry is on near-field effects on the tsunami wave field.

Dislocation Models of Tsunami Generation

Figure 1 shows an example of the coseismic vertical displacement field for a thrust fault: the Sunda thrust during the 2004 M_w 9.2

Sumatra-Andaman earthquake (Geist et al. 2007). In the near field along subduction margins, the field is characterized by negative amplitudes toward shore (i.e., toward the island of Sumatra in Fig. 1) and positive amplitudes toward the open ocean. The zero displacement line is often termed the hinge line. In most cases, the hinge line is offshore, such that coastal subsidence occurs with large-magnitude subduction zone earthquakes, and the first motion of the tsunami broadside from the source is negative (trough phase). Conversely, at locations in the open ocean, the first motion is positive (peak phase). In some cases, the hinge line is onshore, such that there is a coastal uplift and no initial withdrawal of the ocean (e.g., along the Andaman Islands in Fig. 1). In other cases where the rupture area is near the trench, there is no subsidence or uplift of the coastal region (Geist 1999).

Dislocation models were first used to model tsunami generation in the 1970s (e.g., Abe 1973; Fukao and Furumoto 1975; Kanamori 1972). It is a curious historical circumstance that crack models were already well established to address various geophysical problems by this time (e.g., Eshelby 1957), but were never widely used to model tsunami generation. The main advantage of using uniform-slip dislocation models, termed Volterra dislocations (Bilby and Eshelby 1969), is in reference to the mechanical definition of seismic moment (m_0)

$$m_0 = \bar{\mu} \bar{d}_s \Sigma,$$

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 2 Comparison of vertical displacement field from (a) thrust fault (dip=18°) and (b) strike-slip fault (dip=90°). In both cases, depth to

up-dip edge of dislocation is 19 km. Maximum normalized vertical displacements (u_z/δ) are 0.43 and 0.12 for (a) and (b), respectively

where $\bar{\mu}$ is the average shear modulus of rocks surrounding the rupture and $\bar{\delta}_s$ is the average static slip over the area Σ of the fault that ruptured during the earthquake. However, Madariaga (1979) shows that m_0 can also be related to the static stress drop for a crack. The area Σ of a rupture can be estimated from the aftershock distribution or scaled from earthquake magnitude (e.g., Blaser et al. 2010; Geller 1976). Although mean slip is indicated in the definition of m_0 , this is often taken as the value for uniform slip in Volterra dislocation models (i.e., $\delta_{\text{uniform}} = m_0/(\bar{\mu} \Sigma)$).

Analytical expressions have been developed to calculate the coseismic displacement field $\mathbf{u}$ from dislocations with slip vector $\mathbf{s} \equiv \mathbf{u}_i^+ - \mathbf{u}_i^-$, where the plus and minus sign indicate opposite sides of the dislocation. Okada (1985) reviews the expressions derived through 1983 and derives compact expressions applicable to all fault types and non-Poisson solids. Most importantly for tsunami generation, both finite-fault and point-source representations are given for dip-slip faults, the latter useful for computing displacement from heterogeneous slip as described below. The finite-fault expressions can be compared to those developed earlier by Savage and Hastie (1966) for dip-slip faults. Most of the analytic expressions used for tsunami generation are applied to a homogeneous elastic half space, although expressions have also been

developed for a layered media (e.g., Ma and Kuszniir 1994) and for spherical geometry (e.g., Pollitz 1996).

The effect that individual earthquake source parameters have on seafloor displacement varies considerably. The amount of uniform slip assigned to a Volterra dislocation has the largest effect on the magnitude of seafloor displacement, with an approximately linear relationship between slip and maximum vertical displacement (Geist 1999). The dip of the fault primarily affects the polarity of the tsunami wave. With increasing dip of a thrust fault, the amplitude of the negative polarity phase decreases over the hanging wall and increases over the footwall. Geist (1999) gives a complete description of the effect that these and other earthquake source parameters have on seafloor displacement and the associated near-field tsunami.

The effectiveness of strike-slip faults in generating tsunamis relative to dip-slip faults has recently been debated. Although the slip vector is parallel to the surface, there is vertical displacement associated with strike-slip faults, occurring in a quadrupole pattern (see also Fig. 2b). Using a dislocation model, the vertical displacement pattern for dip-slip and strike-slip faults is compared in Fig. 2 for the same amount of slip and depth to the up-dip edge of the dislocation. For this case, the maximum vertical

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 3 Effect of structural heterogeneity of elastic constants on vertical displacement field in the Puget Sound region. Solid rectangle: down-dip

rupture of Seattle fault through high shear modulus rocks. Dashed rectangle: up-dip rupture through low shear modulus sedimentary rocks of the Seattle sedimentary basin

displacement associated with the strike-slip dislocation is approximately a quarter of that for the thrust dislocation. A similar comparison is made using normal-mode theory by Ward (1980) and Okal (1988), which is useful to gauge the far-field response to the different mechanisms.

Rather than using an elastic half-space or layered-earth model, realistic geologic structures and heterogeneous physical properties can be used to calculate seafloor displacement, most often by finite element methods (Geist and Yoshioka 1996;

Masterlark 2003; Zhao et al. 2004). Static elastic deformation models developed for the Nankai subduction zone were adapted to calculate tsunami generation along the Cascadia subduction zone (Geist and Yoshioka 1996). The development of thrust faulting in the presence of subducted seamounts, also at the Nankai subduction zone, is examined using a finite element model by Baba et al. (2001). The effect of sedimentary basins on static elastic displacements is shown for the Seattle basin in Fig. 3 (Geist and Yoshioka 2004). The effect of rupturing into lower-than-average shear

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation,

Fig. 4 Effect of decreasing depth to up-dip edge of rupture (h in kilometers) on vertical displacement (u_z) profile (normalized with respect to slip, δ) for a shallow thrust Volterra dislocation

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation,

Fig. 5 Coordinate system and parameters for crack model

modulus is to increase vertical displacement at the surface (blue region, bottom of Fig. 3), consistent with the results of Ma and Kusznir (1994) and Savage (1998). Finite element models are also critical for calculating dynamic displacements as will be described in the Dynamic Rupture Models section.

Finally, it is important to recognize a prominent artifact associated with dislocation models of shallow imbedded thrust faults, as shown in Fig. 4. Although the expressions for surface displacement developed by Okada (1985) do not include the dislocation edge singularity for faults that rupture to the surface, the short-wavelength effect of the singularity is evident for cases where the up-dip edge is near the surface, relative to the down-dip width of the rupture. In a later study, Okada (1992) discusses

these and other internal singularities further. Application of the $1/\cosh(kh)$ low-pass filter will attenuate this artifact but will lead to a general underestimation of tsunami amplitude. This artifact can be avoided by using crack models for tsunami generation as described in the next section.

Crack Models of Tsunami Generation

Unlike dislocation models for tsunami generation in which slip is prescribed, the slip distribution associated with crack models is calculated and physically consistent with the applied tectonic stresses and frictional conditions on the fault. For dip-slip faults of geometry shown in Fig. 5, the slip gradient in the dip direction $\delta'(\xi)$ is given

by the following singular integral equation (Dmowska and Kostrov 1973):

$$\frac{1}{\pi} \int_a^b \frac{\delta'(s)}{s - \xi} ds + \frac{1}{\pi} \int_a^b K(\xi, s) \delta'(s) ds = \frac{2(1 - \nu)}{\mu} f(\xi),$$

where λ and μ are Lamé's constants, ν is Poisson's ratio, and $f(\xi)$ represents the initial shear stress distribution. In terms of principal stresses, $f(\xi)$ is given by

$$f(\xi) \equiv \sigma_{\xi\eta}^0 = \frac{1}{2}(\sigma_{xx}^0 - \sigma_{zz}^0) \sin 2\alpha + \sigma_{xz}^0 \cos 2\alpha$$

with the zero superscript indicating initial stress.

The effect of decreased normal stress on a shallow imbedded crack makes it more likely to rupture to the surface above a critical depth as shown by Rudnicki and Wu (1995). The Coulomb friction condition is introduced such that slip occurs when $|\sigma_{\xi\eta}| = k\sigma_{\eta\eta}$, where k is the apparent coefficient of friction, including effects of pore-pressure differences in the fault zone. The right-hand side of integral equation above is modified such that

$$f_k(\xi) = f(\xi) - k\sigma_{\eta\eta}^0$$

For shallow imbedded faults, any changes in shear stress at depth will result in normal stress changes up dip, such that the slip distribution becomes skewed up dip until a critical depth when slip is unstable and ruptures through to the surface (Dmowska and Kostrov 1973; Rudnicki and Wu 1995). However, rupture propagation to the surface may be inhibited by inelastic deformation (Roering et al. 1997) and effects of fluids in the fault zone (Chambon and Rudnicki 2001). The added effect of dynamic stress transfer from seismic waves interacting with the fault zone is shown using dynamic rupture models (Oglesby and Archuleta 2000; Oglesby et al. 2000) as detailed below.

Although the singularity in the above equation is integrable, Freund and Barnett (1976) developed a slip distribution associated with the smooth closure condition crack model (Bilby and Eshelby 1969) that has been used for

subduction zone earthquakes and tsunami generation (e.g., Geist and Dmowska 1999; Wang and He 2008). The slip gradient function prescribed by Freund and Barnett (1976) is given by

$$\delta' = \Delta \begin{cases} \frac{12}{q^3} (q\gamma - \gamma^2), & \gamma < q \\ \frac{12}{(1-q)^3} (\gamma^2 - \gamma(1+q) + q), & \gamma > q \end{cases},$$

where Δ is a scaling coefficient, $\gamma \equiv (\xi - a)/(b - a)$, and q ($0 < q < 1$) controls the skewness of the slip distribution. This function satisfies the smooth closure condition $\delta'(a) = \delta'(b) = 0$.

For the specific one-dimensional version of the fault geometry shown in Fig. 5, the displacement profile associated with cracks can be calculated analytically. As indicated by Freund and Barnett (1976), the displacement is calculated by integration based on the slip gradient

$$u_z = \int_a^b U_z(x, s) \delta'_\xi(s) ds,$$

where

$$U_z(x, s) = \frac{xs \sin^2 \alpha}{\pi(x^2 + s^2 - 2xs \cos \alpha)} + \frac{\sin \alpha}{\pi} \tan^{-1} \left(\frac{x - s \cos \alpha}{s \sin \alpha} \right).$$

Calculation of more general surface displacement fields in two dimensions is discussed in the next section.

Using these formulas, the slip gradient can be related to the aspects of the displacement profile. For example, Fig. 6 compares the vertical displacement profile from a shallow imbedded crack to an equivalent dislocation. Crack models avoid the strong fault-tip singularities associated with dislocation models and the associated effects on the seafloor displacement field. The strain singularity at the edge of the dislocation manifests as a short-wavelength spike in the displacement as shown in Fig. 4. Conversely, the concentration of slip in the middle of a crack

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation,

Fig. 6 Comparison of displacement profiles between imbedded crack (dashed line) and dislocation (solid line) models with same average slip (uniform slip for the dislocation model). See Fig. 5 for fault geometry

results in more seafloor displacements over the center of the rupture when compared to the displacement field from the dislocation.

One can also compare a surface-rupturing crack with an equivalent very shallow imbedded crack to show the effect of surface rupture (Fig. 7). The dip-directed slip profile radically changes from a skewed half ellipse to a quarter ellipse with twice the maximum slip when the surface is ruptured (Fig. 7a). The stress drop for the surface-rupturing case is lower under the tectonic stress conditions given above, and the vertical displacement is similar for the two cases. The reason for the latter is that the up-dip slip gradient is higher for the imbedded case than for the surface-rupturing case. The surface-rupturing case results in a fault scarp at the seafloor that is filtered through the water column as mentioned in the Introduction. As the depth to the top of the imbedded crack increases, the peak vertical displacement decreases.

Heterogeneous Static Slip

The surface displacement field associated with cracks and other heterogeneous slip models can generally be computed using the static elastic Green's functions. Consider three components of displacement at a point on the seafloor given

by the location vector $\mathbf{r}(x, y)$ in response to slip on a fault at location $\mathbf{r}_0(\xi, y)$ (Fig. 8). The three components of seafloor displacement in two dimensions can then be given by (Rybicki 1986)

$$u_m(\mathbf{r}) = \iint_{\Sigma} D_i(\mathbf{r}_0) v_j(\mathbf{r}_0) U_m^{ij}(\mathbf{r}, \mathbf{r}_0) d\Sigma \quad m = 1, 2, 3,$$

where $v(\mathbf{r}_0)$ is the surface normal of a fault plane with arbitrary geometry and Σ is the area of the fault plane. For an isotropic medium, the six Green's functions are given by

$$U_m^{ij} = U_m^{ji} = \lambda \delta_{ij} G_m^{n,n} + \mu [G_m^{i,j} + G_m^{j,i}],$$

where λ is Lamé's first constant and δ_{ij} is the Kronecker delta. A review of the static elastic Green's functions G_m^i under different assumptions can be found in Segall (2010).

The displacement field can also be approximated by small dislocation fault elements. Because the elastic deformation is linear at large scales, the displacement field from individual small elements can be superimposed to construct the full displacement field from a rupture. For example, Okada (1985) provides point-source analytic expressions for an element of surface area $\Delta\Sigma$. As shown in Fig. 9, this technique provides a good approximation to the analytic

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation,

Fig. 7 Comparison of slip profiles (a) and displacement profiles (b) between a surface-rupturing crack (solid line) and a very shallow imbedded crack (dashed line). Static stress drop for the two models is 4.8 and 6.3 MPa, respectively. See Fig. 5 for fault geometry

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 8 Coordinate system and parameters for heterogeneous slip model

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation,

displacement profile calculated for a crack if small enough elements are used. Linear superposition of subfault elements also provides the basis for finite-fault inversion using tsunami waveforms (Satake and Kanamori 1991).

The difference in the local tsunami wave field between crack and dislocation models is shown by example in Figs. 10 and 11. In both cases, a 270 km long and 70 km wide, pure thrust rupture is used, with a dip of 20° and average slip of 1 m. For the crack model, the slip distribution is that derived from Freund and Barnett (1976) under smooth closure conditions ($q=0.3$). Details of the modeling procedure are given in Geist and Dmowska (1999). Marigrams (time series plot of wave amplitude) are displayed for both the

local tsunami approaching shore (left) and the outgoing tsunami (right). For all marigrams, the maximum amplitude is higher for the crack model, even though the scalar seismic moment is identical. The dominant period of the tsunami associated with the crack model is also shorter, leading to a higher wave steepness and larger run-up compared to the tsunami from the dislocation model.

Earthquake rupture is often sufficiently complex that it cannot be adequately described by either uniform slip (in the case of the dislocation model) or uniform static stress drop (in the case of the crack model). For this reason, the slip distribution along a fault is difficult to predict without modeling the rupture process itself

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 10 Tsunami wave field using a dislocation model. Uniform slip within a rectangular rupture zone shown at the bottom middle. Initial

wave field, assuming instantaneous rupture, shown in the center. Marigrams on the left side are time series plots of local tsunami approaching shore. Marigrams on the right side represent propagation toward the ocean basin

(next Section). Several stochastic slip models have been developed to simulate static slip in a probabilistic sense (Andrews 1980; Lavallée et al. 2006).

Application of Dynamic Rupture Models to Tsunami Generation

Dynamic models of the earthquake source push the physical assumptions of dislocation models back a step; rather than assuming an instantaneous distribution of slip on the fault, dynamic spontaneous earthquake rupture models start with a distribution of stress and frictional parameters on the fault, along with material properties throughout the medium. A key assumption in

such models is the constitutive law, which determines how the shear stress on the fault depends on quantities such as the normal stress across the fault, the instantaneous slip or slip rate on the fault, as well as the integrated history of the rupture. Such models use the laws of motion and elastodynamics to calculate the time-dependent propagation of rupture and the evolution of slip at each point on the fault, as well as the time-dependent deformation of the earth's surface. In this way, these models are more similar to the crack models mentioned above, but with the added feature that the rupture path, slip distribution, and final size of the earthquake are calculated as a result of the interaction of dynamic stress waves with the frictional and geometrical characteristics of the fault.

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 11 Tsunami wave field using a crack model. Heterogeneous slip within a rectangular rupture zone shown at bottom middle (lighter colors represent higher slip). Initial wave field, assuming

instantaneous rupture, shown in the center. Marigrams on the left side are time series plots of local tsunami approaching shore. Marigrams on the right side represent propagation toward the ocean basin

While dislocation models may assume slip distributions that are not consistent with any physically plausible stress distribution, such consistency is at the heart of dynamic models. Dynamic models have been used extensively in earthquake modeling for both basic physics and ground motion purposes (e.g., Andrews 1976; Das 1981; Day 1982; Harris et al. 1991; Oglesby et al. 1998). A common feature of such models is that if the frictional stress on the fault drops rapidly enough as a function of slip, slip rate, or time, unstable motion is a result. All other factors being equal, high stress drops lead to fast rupture propagation and rapid fault slip, along with high final slip. Zones in which the frictional stress remains constant or increases over the course of the earthquake (such as in the very deep and shallow

portions of a fault) tend to cause rupture and slip to slow down and die out (Okubo 1989).

Spontaneous dynamic rupture models of megathrust earthquakes can shed considerable light on both the physics of the earthquake process and the generation of tsunamis. For example, in such earthquakes, reflected waves from the free surface can reduce the normal stress on the fault during slip, facilitating rupture (Brune 1996; Oglesby et al. 1998). Kozdon and Dunham (2013) show that in the case of the 2011 Tohoku Earthquake, this effect can explain the rupture and high slip all the way to the trench, even in the near-surface zone in which the frictional coefficient is expected to increase with slip rate. Somewhat similarly, Noda and Lapusta (2013) show that ruptures can tunnel through stably

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 12 Fault geometry of Wendt et al. (2009). The splay fault (Faults B and C)

branches off the plate boundary thrust (Fault A) close to shore and at a significantly steeper dip than the plate boundary thrust

E

sliding regions of a fault (i.e., zones with low seismic coupling) if pore-fluid pressurization takes place. The possibility of earthquake rupture and slip propagating into areas that appear to be stably sliding can have important implications for both the distribution of slip in an earthquake and its overall size, with obvious consequences for tsunami generation. Recent dynamic models by Ma and Hirakawa (2013) have argued that failure of material in the hanging-wall wedge might lead to slow rupture propagation and slow slip near the trench, leading to low-radiation, high-tsunami “tsunami earthquakes.”

Fault dynamics can also play an important role in determining rupture path and partitioning of slip between different fault segments in a geometrically complex fault system. An issue of great importance for tsunami generation is that of splay faults – whether a splay fault is activated coseismically. In a standard dislocation or crack model, the decision of whether a splay fault will slip is made a priori and is unconnected with the slip process elsewhere on the fault system. However, Wendt et al. (2009) show that the ability of rupture to propagate to a splay fault is a result of the dynamic rupture process and can have a first-order effect on tsunami generation and near-field run-up. Their fault geometry, motivated by the Nankai Trough, is shown in Fig. 12.

The researchers used the dynamic finite element method (FEM) (Oglesby 1999; Whirley and Engelmann 1993) to perform spontaneous dynamic rupture models of potential earthquakes on this fault system. They found that if stress on the faults is largely homogeneous, rupture proceeds only on the plate boundary thrust. However, if a barrier is present on the plate boundary thrust, rupture

transfers to the steeper splay fault. A comparison between the vertical surface displacement fields in these two cases is shown in Fig. 13.

Because of the more vertically directed hanging-wall movement, the splay faulting case produces a significantly larger vertical seafloor displacement than the homogeneous case. For this reason, the local tsunami in the barrier case produces a significantly larger wave in the near-source region (in this case, along the shore of Japan) than the homogeneous case, as seen in Fig. 14, and it also reaches the near shore much sooner.

It should be noted that in this simple model, the moment of the barrier model (6.8×10^{20} Nm) is less than half that of the homogeneous case (1.8×10^{21} Nm), so the difference in tsunami height is purely due to the rupture path and slip distribution, not to the overall size of the earthquake. Another advantage of the dynamic modeling method in this case is that the partitioning of slip between the plate boundary thrust and the splay fault is a calculated result of the problem rather than an assumption; the method correctly accounts for the fact that slip on the splay suppresses slip on the plate boundary thrust, and vice versa.

The examples given above raise a tantalizing possibility: if enough is known about the geology and fault geometry of a subduction zone, dynamic modeling has the promise to help predict (or at least constrain) the size and severity of potential earthquakes and tsunamis in the region. Someday it may be possible to constrain the likelihood of rupture to the trench or whether rupture is likely to propagate to a splay fault rather than (or in addition to) the main plate boundary thrust

Vertical Seafloor Displacement

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 13 Comparison of vertical seafloor displacement for homogeneous-stress case (*left*) and barrier case (*right*). Note that the barrier case

produces much higher vertical displacement than the homogeneous case and that this displacement is closer to shore

Earthquake Mechanism and Seafloor Deformation for Tsunami Generation, Fig. 14 Comparison of wave amplitude (m) for the homogeneous case (*left*) and

the barrier case (*right*). The rupture of the splay produces a higher initial tsunami as well as higher wave amplitude as the tsunami approaches the shore (*insets*)

fault. In this manner, dynamic models may help to compensate for lack of historical data, especially in the case of extremely large ($M\ 9+$) events that happen only once or twice a millennium. Dynamic models are not a panacea, however Like dislocation and crack models, they rest on assumptions about physical properties (such as stress and friction) that are quite poorly constrained in many cases. However, they do have the advantage of producing physically self-consistent slip and rupture patterns that take into

account important interactions and processes on and near faults. As such, they can serve an important complement to existing standard methods of tsunami source estimation.

Summary

Tsunamis are generated from earthquakes by vertical displacement of the seafloor during earthquake rupture. Four representations of the

earthquake rupture process have been described, in increasing levels of consistency with earthquake physics, for use as tsunami generation models. First, simple uniform-slip dislocation modeling, scaled to the seismic moment of an earthquake, has historically been the most common representation used for tsunami modeling. Second, crack models avoid artifacts that dislocation models have associated with shallow, imbedded thrust faults. Crack models also directly relate slip distribution to tectonic stress conditions and static stress drop of an earthquake. Third, heterogeneous static slip models account for the observed complexity of distribution slip (and stress drop) throughout a rupture zone, primarily through the use of small dislocation elements. Finally, dynamic rupture models provide the most complete and physically consistent representation of the tsunami generation process. Each of these models has been used in both deterministic and probabilistic hazard assessments, although advanced tsunami generation models provide more accuracy and consistency with the known processes of earthquake physics.

Introduction

Seismic waves can be excited by a variety of sources and processes such as impacts, explosions, volcanic mass ejection, underground cavity collapses, fluid migration, atmosphere/ocean coupling, and of course earthquakes. The nature of seismic excitation and subsequent radiation can be isotropic, the same in all directions as in the case of an explosion, or anisotropic, having distinct directional dependence as in the case for earthquakes. It is commonly found that inversions of seismic waveform data for source parameters for earthquakes, explosions, and induced seismicity deviate from either of these fundamental types and are composed of mixtures that may be real, or due to noise in the data, from sparse station coverage, and imperfect knowledge regarding the Earth model used to describe the propagation of seismic energy from source to station. Thus, recovered source parameters are dependent upon the approximations and assumptions made about the wave propagation side of the problem, and care is needed in interpretation, and thorough error and uncertainty analysis is needed, particularly in studies in which deviations from idealized sources are of interest.

There are many approaches for estimating seismic source parameters ranging from solving nonlinear inversions or grid searches for fault parameters such as strike, rake, and dip to linear inversions for a general seismic moment tensor. Gilbert (1970) first proposed the seismic moment tensor for describing the strength of fundamental forces responsible for seismic excitation from earthquakes, and subsequently there have been a multitude of publications describing various approximations, methods, and applications. The seismic moment tensor can be used to describe the radiation from earthquakes, explosions, and more complicated processes that might involve compound fault rupture and combinations of shear tensile failure that occur in mining, geothermal, volcanic, and inducing environments during operations for energy resource recovery. Julian et al. (1998) and Miller et al. (1998) provide a review of seismic moment tensor theory and applications to non-tectonic seismicity.

Considering earthquake sources, methods have been developed for spatially distributed point sources to address the complexity of large earthquakes (e.g., Kikuchi and Kanamori 1991), spatial point sources with time-dependent moment release allowing for both asynchronous (each moment tensor term has an independent time history) and synchronous moment rate (e.g., Stump and Johnson 1977), and the most common application which involves both a spatial and temporal point source, of which there are numerous examples in the literature. There are methods that utilize complete three-component waveforms, the amplitude spectra of surface waves, those that isolate specific seismic phases, and methods that utilize only specific wave amplitudes or ratios of those amplitudes. There are body wave methods, surface wave methods, and normal mode methods. Moment tensor inversions have been used to learn about the largest megathrust earthquakes and are now commonly applied to study microseismicity, with magnitudes less than zero, in a variety of environments. Methods are applied at teleseismic ($R > 3,000$ km), regional, and local distances. There have been applications related to mining and drilling operations that have considered distances much less than 1 km. Seismic moment tensor methods have been developed to operate autonomously, automatically, and in near real time with either segmented waveform data or on continuous streaming data sets. Derived moment tensor solutions are presently being used to inform on strong shaking hazard shortly after the occurrence of an earthquake, where automated solutions are available minutes following earthquake occurrence in regional distance monitoring situations and within 15–30 min in global/teleseismic monitoring situations. Methods have been implemented in this fashion by international government organizations tasked with seismic monitoring as well as by academia and the private sector. There are many applications and subtleties in approach described in an extensive literature. Jost and Herrmann (1989) provide an excellent theoretical overview and tutorial on the seismic moment tensor method. In this chapter an overview of seismic mechanisms and the

seismic moment tensor method is presented for the case of spatial and temporal point sources.

Construction of Single-Force, Single-Couple, and Double-Couple Radiation Patterns

To study the earthquake mechanism, a Green's function solution of the vector wave (Eq. 1) that assumes a homogeneous isotropic elastic whole space is begun with:

$$(\lambda + 2\mu)\nabla(\nabla \cdot \vec{u}) - \mu\nabla \times \nabla \times \vec{u} + \vec{f} = \rho \ddot{\vec{u}} \quad (1)$$

u is the vector displacement for a unit force, f , in an isotropic elastic medium defined by the Lamé coefficients, λ and μ , and the density, ρ . The solution to the forced vector wave equation may be written as follows (Aki and Richards 1980):

$$\begin{aligned} u_n(r, t) = & \frac{3\gamma_n\gamma_p - \delta_{np}}{4\pi\rho r^3} \int_{r/\alpha}^{r/\beta} \tau F(t - \tau) d\tau \\ & + \frac{\gamma_n\gamma_p}{4\pi\rho\alpha^2 r} F(t - r/\alpha) \\ & - \frac{\gamma_n\gamma_p - \delta_{np}}{4\pi\rho\beta^2 r} F(t - r/\beta) \end{aligned} \quad (2)$$

This equation relates the n th component of displacement to the near-field (first term on right), the far-field P-wave, and the far-field S-wave radiation for a unit force in the p -direction. α and β are the P- and S-wave velocities, δ is the Kronecker delta function, and γ are direction cosines relating the direction of ground motion, n , to the direction of the unit force, p . The far-field terms are proportional to the applied force, and the near-field term is proportional to its integral. Single-force solutions may be used to study the seismic excitation due to an impact, mass ejection (Kanamori et al. 1984), or landslides (e.g., Kawakatsu 1989). Other types of seismic excitation are described by combinations of dipole forces, which are obtained by taking spatial derivatives of the single-force solutions, as described below.

Earthquake Mechanism Description and Inversion, Fig. 1 P- and S-wave radiation patterns for a single couple

The distance between the observation point and the location of the unit force is given by

$$r = \left[(x_1 - \zeta_1)^2 + (x_2 - \zeta_2)^2 + (x_3 - \zeta_3)^2 \right]^{1/2}. \quad (3)$$

The solution for the double-couple earthquake mechanism is obtained by taking spatial derivatives of Eq. 2 with respect to the source coordinate, where $\partial r / \partial \zeta_j = -\gamma_j$. Partial derivatives with respect to $1/r$, $1/r^3$ and the direction cosines yield additional near-field terms, whereas the partial derivative of the force time history yields

$$\frac{\partial F(t - r/\alpha)}{\partial \zeta_j} = -\frac{\gamma_j \dot{F}(t - r/\alpha)}{\alpha}, \quad (4)$$

and the far-field term for the P-wave may be written as

$$u_n^{SC}(r, t) = \frac{\gamma_n\gamma_p\gamma_j \dot{M}(t - r/\alpha)}{4\pi\rho\alpha^3 r}, \quad (5)$$

where $\dot{M}$ is the moment rate (Nm/s).

Figure 1 compares the single-couple radiation patterns for P- and S-waves. While the P-wave displays a four-lobed radiation pattern consistent

with observation, the S-wave has only a two-lobed pattern. A double-couple solution is found simply by constructing single-couple solutions for two orthogonal directions and summing. For both the P- and S-wave cases, if a single force in the $p = 1$ direction is considered and a derivative taken in $j = 3$ and summed up with a single force for $p = 3$ and a derivative in $j = 1$, the following far-field, double-couple solutions are found:

$$u_n^{\text{DC-Pwave}}(r, t) = \frac{\gamma_n \gamma_1 \gamma_3 \dot{M}(t - r/\alpha)}{4\pi\rho\alpha^3 r} \hat{x}_n + \frac{\gamma_n \gamma_3 \gamma_1 \dot{M}(t - r/\alpha)}{4\pi\rho\alpha^3 r} \hat{x}_n$$

$$u_n^{\text{DC-Swave}}(r, t) = \frac{(\delta_{n1} - \gamma_n \gamma_1) \gamma_3 \dot{M}(t - r/\beta)}{4\pi\rho\beta^3 r} \hat{x}_n + \frac{(\delta_{n1} - \gamma_n \gamma_3) \gamma_1 \dot{M}(t - r/\beta)}{4\pi\rho\beta^3 r} \hat{x}_n \quad (6)$$

Figure 2 compares the P- and S-wave radiation patterns for a double couple in the x_1x_3 plane using Eq. 6. Both the P- and S-waves display two-lobed radiation patterns consistent with observation. As shown in Aki and Richards (1980), the spatial derivatives may be carried out on all terms leading to a solution to Eq. 1 comprised of near-field, intermediate, and far-field terms ($1/r^4$, $1/r^2$, $1/r$), all of which can be represented in terms of direction cosines, strike, rake, and dip parameters of a double-couple mechanism, or more generally as a seismic moment tensor (Aki and Richards 1980).

It is common to represent the mechanism of an earthquake in terms of the P-wave radiation pattern using a focal sphere representation. An example of such a representation is given in Fig. 3 in which the lower hemisphere is presented. There are four quadrants as found in Eq. 6 and Fig. 2. The shaded quadrants indicate a P-wave first arrival with a vertical component polarity that is up, whereas the unshaded quadrants indicate a first motion that is down. In this

Earthquake Mechanism Description and Inversion, Fig. 2 P- and S-wave radiation patterns for a double couple

hemispherical representation, the horizontal angle represents the azimuth from north, and the vertical angle represents the direction that a P-wave ray leaves the source, where an angle of zero indicates a ray leaving straight down and an angle of 90° indicates a wave leaving horizontally. This representation is useful for conveying earthquake mechanism information in map view for analysis of the tectonics of a region.

The solutions given by Eq. 6 are for a homogeneous and isotropic elastic whole space. In the next section it is shown that more general source solutions can be characterized by the seismic moment tensor for more complex elastic structure using appropriate numerical methods to compute Green's functions.

Generalized Seismic Moment Tensor

The impulse response to Eq. 1 or more generally for 1-D, 2-D, and 3-D earth structures is referred to as the Green's function solution to the elastodynamic equation of motion. Green's functions may be found for volume distributed forces, for distributed shear dislocation on an interior

surface, or for traction acting on an exterior surface. The general representation theorem for a shear dislocation over an interior surface (Σ) within an elastic body is written as

$$u_n(\bar{x}, t) = \int d\tau \iint [u_i(\tau, \bar{\zeta})] \hat{v}_j C_{ijkl} \cdot G_{nk,l}(t - \tau, \bar{x}; 0, \bar{\zeta}) d\Sigma$$

$$u_n(\bar{x}, t) = \int d\tau \iint M_{ij}(\tau, \bar{\zeta}) \cdot G_{ni,j}(t - \tau, \bar{x}; 0, \bar{\zeta}) d\Sigma \quad (7)$$

where $[u_i(\tau, \bar{\zeta})]$ is the displacement discontinuity across a surface oriented with the unit vector normal, $\hat{v}_j$. C_{ijkl} is the elastic tensor, and $G_{nk,l}$ is

Green's tensor of single-couple solutions where n is the ground motion component, k is the direction of a unit force, and l is the direction

Earthquake Mechanism Description and Inversion,
Fig. 4 Schematic showing the system of single couples and vector dipoles comprising the seismic moment tensor.

Note that the values of M_{ij} , representing the strength of these source terms, are both real and symmetric

of the spatial derivative of the single force. See Aki and Richards (1980) for a thorough discussion of the general representation theorem of seismic sources. Equivalently, the representation theorem can be written in terms of the moment tensor (M_{ij}) distributed spatially and temporally over Σ (Eq. 7). Figure 4 illustrates the system of single couples and linear vector dipoles represented by both $G_{ni,j}$ and M_{ij} . Given a number of observations, the representation theorem provides a system of equations that if given Green's functions for 1-D, 2-D, or

even 3-D earth models, the spatiotemporal distribution of fault slip, $[u]$, may be obtained through inversion (e.g., Hartzel and Heaton 1983). There are numerous linear, linearized, and nonlinear approaches to solve this system of equations each considering different approximations on how to kinematically represent the spatiotemporal integration of the seismic source.

If a source is considered to be a point in space, in which the wavelengths of observed seismic waves are considerably larger than the

source dimension, then the spatial integral is unnecessary, and

$$\begin{aligned} u_n(\vec{x}, t) &= \int M_{ij}(\tau) G_{ni,j}(t - \tau, \vec{x}) d\tau & (a) \\ u_n(\vec{x}, t) &= \int M_{ij} \cdot S(\tau) G_{ni,j}(t - \tau, \vec{x}) d\tau & (b), \\ u_n(\vec{x}, t) &= M_{ij} G_{ni,j}(t, \vec{x}) & (c) \end{aligned} \quad (8)$$

which accounts for the general case in which each term of the moment tensor can have a different source time history (Eq. 8a), as well as the simplified case in which each element is assumed to have the same, or synchronous, time history (Eq. 8b).

The most commonly applied solution is a synchronous source in which the time history is considered to be a delta function yielding the

linear system of equations employed in seismic moment tensor analysis (Eq. 8c).

The strength of the individual single-couple and vector-dipole Green's function solutions ($G_{ni,j}$) is given by M_{ij} which is a second-order tensor that is both real and symmetric ($M_{12} = M_{21}$) enabling the decomposition into three orthogonal eigenvectors:

$$M_{ij} = \begin{pmatrix} M_{11} & M_{12} & M_{13} \\ M_{21} & M_{22} & M_{23} \\ M_{31} & M_{32} & M_{33} \end{pmatrix} \quad (9)$$

Equation 8c is a linear system of equations that is overdetermined with three-component seismic waveform data, even with low-pass filters applied. Writing this in terms of a system of linear equations, the following is obtained:

$$GM = u$$

$$\begin{pmatrix} G_{11,1} & G_{11,2} & G_{11,3} & G_{12,2} & G_{12,3} & G_{13,3} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ G_{N1,1} & G_{N1,2} & G_{N1,3} & G_{N2,2} & G_{N2,3} & G_{N3,3} \end{pmatrix} \begin{pmatrix} M_{11} \\ M_{12} \\ M_{13} \\ M_{22} \\ M_{23} \\ M_{33} \end{pmatrix} = \begin{pmatrix} u_1 \\ u_2 \\ \vdots \\ u_N \end{pmatrix} \quad (10)$$

Here, N refers to the total of number of stations by components by samples of the observed waveforms and computed Green's functions. This system of equations can be solved by finding the generalized inverse where

$$M = (G^T G)^{-1} G^T u, \quad (11)$$

in which G is an $N \times 6$ or $N \times 5$ matrix where there are 5 or 6 independent moment tensor source parameters representing the strength of fundamental couples. All 6 parameters must be solved for if volumetric sources are to be considered. If a deviatoric solution is desired, then there are only 5 independent elements of the moment tensor and the constraint $M_{33} = -(M_{11} + M_{22})$ is applied.

Decomposition

While the solution of Eq. 11 is unique, the decomposition and interpretation of the moment tensor is not. The seismic moment tensor with 6 independent elements can be decomposed into its principle axes by performing an eigenvector decomposition. Each eigenvalue then represents the strength of the principle eigenvectors or source vector dipoles. Thus, a moment tensor can be decomposed into three mutually orthogonal vector dipoles. These vector dipoles can be combined to produce a double couple in which two of the eigenvalues have equal magnitude but opposite sign and where the third has zero strength. In the case of three nonzero eigenvalues, there are numerous ways that the vector dipoles can be combined to produce combinations of double couples, systems of volume compensated

Earthquake Mechanism Description and Inversion,

Fig. 5 Relationships between eigenvalues for the three fundamental moment tensor types

E

vector dipoles (CLVD; Knopoff and Randall 1970), and combinations of DCs and CLVDs that sum to yield the same moment tensor. Figure 5 illustrates combinations of vector dipoles leading to spherically symmetric isotropic radiation, a double couple, and a CLVD. Julian et al. (1998) give a detailed description of the different decomposition possibilities and the radiation characteristics of each type of source, and Jost and Herrmann (1989) give a thorough discussion of the moment tensor theory, seismic waveform inverse procedure, and decomposition schemes for several common cases.

Here, the isotropic, double-couple, and CLVD decomposition are given. For the general 6 parameter moment tensor (M), the isotropic moment tensor ($M_0^I I$) representing volume change is subtracted leaving the deviatoric moment tensor (M^D), where

$$M^D = M - M_0^I I \quad (12)$$

and I is the diagonal matrix. The isotropic scalar moment is defined as

$$M_0^I = (M_{11} + M_{22} + M_{33})/3. \quad (13)$$

M^D is then solved for its three orthogonal eigenvectors (a_i) and eigenvalues (m_i), which are then ranked.

$$|m_3| \geq |m_2| \geq |m_1| \quad (14)$$

There are several methods for determining the scalar seismic moment either directly from the moment tensor or from its eigenvalues (Aki and Richards 1980). Traditionally the method of Dziewonski and Woodhouse (1983) has been used where

$$M_0^{DW} = \frac{|m_3| + |m_2|}{2}. \quad (15)$$

Alternatively Bowers and Hudson (1999) define the total scalar moment (M_0^T) as the sum of the isotropic moment and the largest deviatoric eigenvalue, which provides an estimate equivalent to M_0^{DW} for double couples, but provides better estimates for sources that deviate from a simple double couple for tectonic earthquakes such as the CLVD and tensile crack.

$$M_0^T = M_0^I + |m_3| \quad (16)$$

As Julian et al. (1998) point out, the decomposition of the seismic moment tensor is necessary for interpretation but is also non-unique. Today the most common decomposition approach is one in which the deviatoric moment tensor is decomposed into a double couple and a CLVD, each with the same compression (P) and tension (T) axes, following Knopoff and Randall (1970).

To decompose the moment tensor in this way, after first removing the isotropic component

Earthquake Mechanism Description and Inversion, Fig. 6 Equal area source-type plot from Bowers and Hudson (1999). Specific (T, k) values are plotted in the source-type space with the corresponding fundamental source types, where the DC point represents all double couples, CLVD has a major vector dipole in tension and

–CLVD in compression, TC and –TC are tensile and closing cracks, LVD are linear vector dipoles, and the *top* and *bottom* of the plot show the position of explosion and implosions. All other points can be interpreted as mixtures of these fundamental source types

(Eq. 12), ranking the deviatoric eigenvalues (Eq. 14), the ratio of the maximum to minimum deviatoric eigenvalue is found where

$$F = \left| \frac{m_1}{m_3} \right| \quad (17)$$

F is used to scale the scalar moment of the double-couple and CLVD components, and the complete moment tensor (M) is then represented as

$$M = M_0^I \cdot I + (1 - 2F) \cdot m_3 \cdot (a_3 a_3 - a_2 a_2) + F \cdot m_3 \cdot (2a_3 a_3 - a_2 a_2 - a_1 a_1), \quad (18)$$

$a_3 a_3$, etc. are dyadics of the eigenvectors, matrices describing the orientations of the principal vector dipoles.

The resulting decomposition can also be characterized in terms of the percentage of moment in

each of the fundamental components. Based on the total scalar moment (Eq. 16), the following defines the percentages of the isotropic, double couple, and CVLD for the decomposition given by Eq. 18:

$$\begin{aligned} \text{Piso} &= \frac{|M_0^I|}{|M_0^T|} \cdot 100\% \\ \text{Pdc} &= (100 - \text{Piso}) \cdot (1 - 2F)\% \\ \text{Pclvd} &= (100 - \text{Piso}) \cdot 2F\% \end{aligned} \quad (19)$$

Representation Methods

Because the choice of the particular decomposition method is non-unique (e.g., Jost and Herrmann 1989; Julian et al. 1998), there is a growing interest in using graphical representations of the moment tensor eigenvalues (Hudson et al. 1989; Riedesel and Jordan 1989; Tape and Tape 2012). For example, the source-type diagram of Hudson et al. (1989) examines ratios of the three eigenvalues of the moment tensor decomposition to

Earthquake Mechanism Description and Inversion, Fig. 7 Comparison of long-period (20–50 s) three-component, complete waveforms for a tectonic earthquake on the Hayward Fault, California. The solution is

predominantly double couple. The NSS shows a wide area of acceptable solutions due to the relatively small number of stations used. The distribution of best solutions is centered on a double couple

find a scaling for a volumetric component (κ) and a deviation from a pure double-couple deviatoric solution (T) (Eq. 20). The values are plotted in a Cartesian coordinate system that is deformed to provide an equal area representation of κ and T . The advantage of this approach and the others is that a solution may be analyzed in terms of its proximity to idealized, fundamental solution types on the diagram, as well as providing a representation enabling the analysis of both

epistemic and aleatoric uncertainties in the solutions (e.g., Ford et al. 2010):

$$T = \frac{2m_1}{|m_3|}, \quad k = \frac{M'_0}{M'_0 + |m_3|} \quad (20)$$

Figure 6 illustrates the source-type projection with the position of fundamental source types identified (DC, CLVD, TC, LVD, and explosion).

Earthquake Mechanism Description and Inversion, Fig. 8 Comparison of long-period (20–50 s) three-component, complete waveforms for an earthquake in Long Valley Caldera, California. The deviatoric solution has a large CLVD, and the full moment tensor (shown) has

a large volume increase component. The NSS shows the best solutions are substantially shifted from the deviatoric line (+CLVD-DC-CLVD). The improvement in fit afforded by the volume increase component is statistically significant based on the F-test

The DC point represents all possible double-couple solutions. Positive and negative CLVD sources are for the cases with a major vector dipole in tension (example given in Fig. 5) and compression, respectively. Similarly, the linear-vector-dipole (LVD) and tension crack

(TC) solutions plot in distinct locations on the graph. All other points can be considered to be mixtures of these fundamental types. Shear tensile cracks (e.g., Šílený, J., and J. Kozák (1988) can be thought to lie along the line connecting the TC and -TC source types that passes through the

origin (DC). Julian et al. (1998) demonstrate that other locations can be interpreted as shear tensile cracks in which the two elements of the crack are not coplanar and have different geometries.

Example of a Seismic Moment Tensor Inversion for Double-Couple and Non-Double-Couple Cases

This section illustrates the inversion of three-component waveform data for the seismic moment tensor. A full moment tensor is solved for an earthquake located on the Hayward Fault in California. The broadband velocity data were instrument corrected, integrated to displacement, and filtered with an acausal, bandpass, Butterworth filter with corners set at 0.02 and 0.05 Hz. Green's functions were computed for an appropriate layered velocity structure using a frequency-wavenumber integration method and were bandpass filtered with the same filter applied to the data. Figure 7 shows the fit to the data, the P-wave radiation pattern, and pertinent source information. This earthquake is a tectonic earthquake and the solution is predominantly double couple. The small CLVD and volume increase components are due to noise and epistemic uncertainty.

The network sensitivity solution (NSS; Ford et al. 2010) is also presented. An NSS represents a maximum fit surface in the source-type space. It is computed by finding the best fit solution for each T and κ point. The fit is measured by a variance reduction. The NSS for this event shows a relatively wide distribution that is centered at a double couple but extends substantially into regions with either non-double-couple deviatoric solutions or solutions that have volume change components. This is due to the fact that only three stations were used and demonstrates uncertainty in the solution in terms of the more difficult to recover non-double-couple components. In this case non-double-couple and volumetric sources are not statistically significant.

In Fig. 8 a moment tensor solution for an earthquake from Long Valley Caldera, California, during a period of heightened seismic,

deformation, and CO_2 gas flux is presented (Dreger et al. 2000; Minson and Dreger 2008). The data processing is the same as in the previous example. The solution indicates a large volume increase component that has been found to be statistically significant using an F-test. The NSS shows the best fit region is shifted substantially from the deviatoric line.

Earthquake Mechanisms and Stress Field

Dynamics and mechanics of faulting; Earthquake source observations; Focal mechanism; Rock failure; Shear faulting; Tectonic stress; Tensile faulting

Introduction

Earthquakes are processes associated with the sudden rupture of rocks along cracks, fractures or faults exposed to stress field in the Earth's crust and lithosphere. If stress reaches a critical value exceeding strength of faults or fractures in rock, accumulated energy of elastic deformation is partially spent for anelastic deformations in the focal zone and partially released and radiated in the form of seismic waves. Stress in the Earth's crust causing earthquakes can be of tectonic or non-tectonic origin (Ruff 2002; Zoback 2007; Zang and Stephansson 2010). The main source of non-tectonic stress within the Earth is gravitational loading. This stress is vertical with largest lateral variations near the Earth's surface being more homogeneous at depth. On the other hand,

tectonic stress is mostly horizontal and originates in forces driving the plate motions (Heidbach et al. 2008). These forces typically cause “ridge push” processes where lithospheric plates are pushed to move away from spreading ridge or “slab pull” processes where two plates are in collision and one of them is subducting into the asthenosphere (Fowler 1990). The global plate tectonics successfully explained concentration of large earthquakes on margins of the plates characterized by the presence of low strength zones exposed to large stresses. On regional and local scales, stress in the Earth's crust is also affected by topography and its compensation at depth, sediment loading or presence of any heterogeneity caused by variations of density, rigidity and rock rheology, by fluid flow in rocks or by presence of faults, cracks and micro-cracks in rocks.

Properties of the stress field and of the associated fracture processes in the Earth's crust are closely related (Scholz 2002). The most common type of fracturing is shear faulting but under special stress conditions also tensile faulting can be observed (Julian et al. 1998; Vavryčuk 2011b; see entry “► [Non-Double-Couple Earthquakes](#)”). Type of faulting depends on the stress field but also on the orientation of activated fractures or faults with respect to the stress (Vavryčuk 2011a). In addition, the slip vector for shear faulting is close to or coincides with the direction of the maximum shear stress acting on the fault (Wallace 1951; Bott 1959). Therefore, type of faulting, orientation of activated faults and direction of slip along activated faults serve as an important source of information about the stress field and its spatial and lateral variations within the Earth's crust.

In this entry, the basic concept of stress is introduced and its relation to earthquake mechanisms is explained (for description of focal mechanisms, see entry “► [Earthquake Mechanism Description and Inversion](#)”). Mohr's circle diagram and simple failure criteria are described and used for defining the fault instability, principal faults and principal focal mechanisms. Methods of determining stress from observed earthquake mechanisms are reported and their robustness is

Earthquake Mechanisms and Stress Field, Fig. 1 Definition of the stress tensor in original Cartesian coordinate system (a) and in the rotated system of principal stress directions (b)

exemplified on numerical tests. Finally, several applications of stress inversions from earthquake mechanisms are listed.

of forces in a body which causes its deformation but not rotation, the stress tensor must be symmetric

$$\tau_{ij} = \tau_{ji}, \quad (5)$$

Mathematical Description of Stress

Definition of Stress

Stress describes forces acting on a unit surface in a body (see Fig. 1a). Since the acting force and the normal of the unit surface are vectors, the stress is a tensor described by nine components

$$\boldsymbol{\tau} = \begin{bmatrix} \tau_{11} & \tau_{12} & \tau_{13} \\ \tau_{21} & \tau_{22} & \tau_{23} \\ \tau_{31} & \tau_{32} & \tau_{33} \end{bmatrix}. \quad (1)$$

The force acting on surface S with normal $\mathbf{n}$ is called traction $\mathbf{T}$, and it is expressed as

$$T_i = \tau_{ij}n_j \quad (2)$$

with its normal and shear components σ_n and τ

$$\sigma_n = T_i n_i = \tau_{ij}n_i n_j, \quad (3)$$

$$\begin{aligned} \tau N_i &= T_i - \sigma_n n_i = \tau_{ij}n_j - \tau_{jk}n_j n_k n_i \\ &= \tau_{kj}n_j(\delta_{ik} - n_i n_k), \end{aligned} \quad (4)$$

where $\mathbf{N}$ is the direction of shear component τ and lies in surface S . Since stress is defined as that part

being described by six independent components only.

Mohr's Circle Diagram

The values of the stress tensor components depend on the system of coordinates, in which the components are measured. The coordinate system can always be rotated in the way that the stress tensor diagonalizes:

$$\boldsymbol{\tau} = \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix}, \quad (6)$$

where σ_1 , σ_2 and σ_3 are called the maximum, intermediate and minimum principal stresses (compression is positive):

$$\sigma_1 \geq \sigma_2 \geq \sigma_3, \quad (7)$$

and the vectors defining this special coordinate system are called the principal stress directions or principal stress axes (see Fig. 1b). Mathematically, the principal stresses and their directions are found by calculating the eigenvalues and eigenvectors of the stress tensor.

Earthquake Mechanisms and Stress Field, Fig. 2 Mohr's circle diagram. Quantities σ_n and τ are the normal and shear stresses along a fault, σ_1 , σ_2 and σ_3 are the principal stresses. All permissible values of σ_n and τ acting on a fault must lie in the shaded area of the diagram

The normal and shear components σ_n and τ of traction **T** (also called the normal and shear stresses) read in the system of principal stress directions

$$\sigma_n = \sigma_1 n_1^2 + \sigma_2 n_2^2 + \sigma_3 n_3^2, \quad (8)$$

$$\tau^2 = \sigma_1^2 n_1^2 + \sigma_2^2 n_2^2 + \sigma_3^2 n_3^2 - \sigma_n^2. \quad (9)$$

If principal stresses σ_1 , σ_2 and σ_3 are fixed, then normal and shear stresses σ_n and τ are just functions of normal **n** of a fault and can be plotted in the Mohr's circle diagram (see Fig. 2). All permissible values of σ_n and τ must lie in the shaded area of the diagram (Jaeger et al. 2007; Mavko et al. 2009). If the sign of shear stress τ is important in the stress analysis, the Mohr's diagram is not plotted using semi-circles but full circles, see below.

When stress conditions in real rocks in the Earth's crust are studied, the Mohr's diagram is modified. Rocks are typically porous and contain pressurized fluids which influence overall stress in the rock (Scholz 2002). For example, fluids present inside a fault reduce the normal stress along the fault. If the fluid pressure is sufficiently high, fluids can even cause opening of the fault (see Fig. 3a). For this reason, effective normal stress σ is introduced as a difference between normal stress σ_n and pore-fluid pressure p

$$\sigma = \sigma_n - p, \quad (10)$$

and the Mohr's circle diagram is plotted in the σ - τ plane. Variation of pore-fluid pressure in the rock is projected into shifting of the Mohr's diagram along the σ -axis. The pore-fluid pressure acts against the compressive normal stress and Mohr's circles are moved to the left with increasing pore-fluid pressure (see Fig. 3b).

Tectonic Stress and Faulting Regimes

Principal stress directions in the Earth's crust are frequently close to vertical and horizontal directions. This lead Anderson (1951) to developing a simple scheme connecting the basic stress regimes in the Earth's crust with type of faulting on a pre-existing fault in the crust (see Fig. 4). Anderson (1951) distinguishes three possible combinations of magnitudes of principal stresses: the vertical stress is maximum, intermediate or minimum with respect to the horizontal stresses. If the vertical stress is maximum, the hanging wall is moving downwards with respect to the foot wall and the normal faulting is observed along a deeply steeping fault. If the vertical stress is minimum, the crust is in horizontal compression and the hanging wall is moving upwards with respect to the foot wall and reverse faulting is observed along a shallow dipping fault. Finally, if the vertical stress is intermediate, the foot and hanging walls are moving horizontally and the strike slip faulting is observed along a nearly vertical fault. Obviously, the Anderson's classification is simple and does not cover all observations but still it proved to be valid for many seismically active regions and helpful for rough assessment of stress regime (Simpson 1997; Hardebeck and Michael 2006; see entry "► Earthquake Mechanisms and Tectonics").

Rock Failure and Earthquakes

If a rock is critically stressed in the Earth's crust, the rock is fractured and this fracturing is associated with an earthquake. In principle, an

Earthquake Mechanisms and Stress Field, Fig. 3 Role of pore-fluid pressure in the rock. (a) Opening of the fault caused by fluids. (b) Shift of Mohr's circles due to increase of pore-fluid pressure. Σ is the fault, u is

the slip vector and α is the deviation between the slip vector and the fault (the so-called slope angle, see Vavryčuk 2011b)

(right). The focal mechanisms with the P and T axes are shown in the lower-hemisphere equal-area projection

Earthquake Mechanisms and Stress Field, Fig. 5 Griffith failure criterion. (a) Scheme of a cylindrical specimen with a fracture created by loading with stresses $\sigma_1 > \sigma_2 = \sigma_3$ (left) and the corresponding Mohr's circle diagram (right). (b) Position of different

faulting regimes on the Mohr failure envelope $\tau_c(\sigma)$. Point 1 – pure tensile faulting, points 2 – transition between tensile and pure shear faulting, points 3 – pure shear faulting. Angle θ defines the deviation of the fracture from the σ_1 direction, T_0 is the uniaxial tensile strength

earthquake can occur on a newly developed fracture or on a pre-existing fault in the Earth's crust which is re-activated. The condition under which fracturing or faulting occurs is described by the so-called failure criteria. The simplest and most known criteria are the Griffith failure criterion derived from energy conditions imposed on propagating cracks in a rock, and the Mohr-Coulomb failure criterion (also called the Coulomb failure criterion) based on the concept of friction between two sliding blocks simulating the case of faulting on a pre-existing fault. Both failure criteria predict critical values of shear stress as a function of normal stress which lead to failure

$$\tau_c = f(\sigma). \quad (11)$$

They can be plotted as the so called Mohr failure envelopes in the σ - τ diagram together with Mohr's circles and employed for analysis of stability of fractures or faults under given stress conditions. If the outer Mohr's circle touches the failure envelope, there is one fracture or fault which is unstable and can fail, its orientation being defined by inclination θ of the fault from the maximum stress direction (see Fig. 5a).

Griffith Failure Criterion

The Griffith theory of fracture predicts the failure envelope in the following form (Jaeger et al. 2007, Eq. 10.139):

$$\tau_c^2 = 4T_0(T_0 + \sigma), \quad (12)$$

where T_0 is the uniaxial tensile strength. The criterion is described by a parabola with the most curved part close to tensile normal stresses. The point at the parabola with the lowest value of normal stress (point 1 in Fig. 5b) corresponds to fracture lying along the maximum principal stress direction (maximum compression) σ_1 and opening during the fracture process. This physically describes the case of a pure tensile crack created, for example, by hydrofracturing due to fluid injection into the rock mass (Zoback 2007). The intersection of the parabola with the τ -axis (points 2 in Fig. 5b) defines the transition between tensile and shear modes of faulting and corresponds to fracture orientation which can be found using the following simple formula (Fischer and Guest 2011):

$$\tan 2\theta_{\text{tensile}} = \left. \frac{\partial \tau_c}{\partial \sigma} \right|_{\sigma=0} = \left. \frac{\sqrt{T_0}}{\sqrt{T_0 + \sigma}} \right|_{\sigma=0} = 1, \quad (13)$$

and consequently $\theta_{\text{tensile}} = 22.5^\circ$. Hence, tensile faulting (called also shear-tensile faulting) associated with fault opening can occur only for fractures which deviate from the direction of maximum compression with angle lower than θ_{tensile} (Mohr failure envelope between points 1 and 2 in Fig. 5b). For angles equal to or higher than θ_{tensile} only shear faulting mode can be observed (e.g., points 3 in Fig. 5b). As seen from Fig. 5b, the parabola is less curved for angles higher than θ_{tensile} and the Griffith failure criterion can be well approximated by the linear Mohr-Coulomb failure criterion, see below.

Mohr-Coulomb Failure Criterion

According to the Mohr-Coulomb failure criterion (Scholz 2002; Zoback 2007), shear stress on an activated fault must exceed critical value τ_c , which is calculated from cohesion C , fault friction μ and effective normal stress σ :

$$\tau_c = C + \mu\sigma, \quad (14)$$

or equivalently

$$\tau_c = C + \mu(\sigma_n - p), \quad (15)$$

where σ_n is the normal stress and p is the pore pressure. Friction μ for fractures was measured on rock samples in laboratory and ranges mostly between 0.6 and 0.8 (Byerlee 1978). The values of friction of faults in the Earth's crust are similar (Vavryčuk 2011a) but lower values like 0.2–0.4 have also been reported for some large-scale faults like the San Andreas fault (Scholz 2002).

If the Mohr-Coulomb failure criterion is satisfied (red area in Fig. 6), the fault becomes unstable and an earthquake occurs along this fault. The higher the shear stress difference, $\Delta\tau = \tau - \tau_c$, the higher the instability of the fault and the higher the susceptibility of the fault to be activated. A fault most susceptible to failure is called the “principal” fault (Vavryčuk 2011a) being defined by the point in which the Mohr-Coulomb failure criterion touches the Mohr's circle diagram (blue point in Fig. 6)

Earthquake Mechanisms and Stress Field, Fig. 6 Mohr-Coulomb failure criterion. The red area shows all possible orientations of fault planes which satisfy the Mohr-Coulomb failure criterion. The blue dot with shear and normal stresses τ_c and σ_c denotes the principal fault plane which is optimally oriented with respect to stress, and C denotes the cohesion

A variety in possible orientations of unstable fault planes is demonstrated in Fig. 7. The left-hand plot of Fig. 7a shows the Mohr's diagram, the failure criterion and the positions of randomly distributed unstable fault planes satisfying the failure criterion. The middle and right-hand plots of Fig. 7a show the nodal lines and the P (pressure) and T (tension) axes for the corresponding focal mechanisms. The nodal lines and P/T axes inform about the predominant type of faulting and about the scatter in orientations of the unstable fault planes. Predominant faulting and its scatter are also projected into a scatter of the P/T axes, which form clusters of a specific shape and size (Fig. 7a, right-hand plot). The form of the clusters is best demonstrated using the projection of the Mohr-Coulomb failure criterion (Fig. 7b, blue line in the left-hand plot) onto the focal sphere (Fig. 7b, right-hand plot). The failure criterion curve splits into two closed curves for the P axes as well as for the T axes on the focal sphere corresponding to the failure conditions in the upper and lower half-planes in the Mohr's circle diagram. The two P/T failure

Earthquake Mechanisms and Stress Field, Fig. 7 Focal mechanisms associated with unstable fault planes. (a) Randomly distributed fault planes inside the unstable area of the Mohr's diagram (left), corresponding nodal lines (in the middle) and the P/T axes (right). The P (pressure) axes are marked by the red circles, the T - (tension) axes by the blue crosses. (b) Fault planes corresponding to the Mohr failure envelope in the

Mohr's diagram (left), corresponding nodal lines (in the middle) and the P/T axes (right). The P/T axes form the P (red)/T (blue) failure curves displaying the two-wing pattern. The σ_1 , σ_2 and σ_3 stress axes have directions (azimuth/plunge): $308^\circ/44^\circ$, $209^\circ/9^\circ$ and $110^\circ/44^\circ$. The shape ratio R is 0.5. The azimuth angle is measured clockwise from north (denoted as N), and the plunge angle from the horizontal plane

curves may intersect each other or be separated. The area inside the failure curves define positions of the P/T axes of focal mechanisms conceivable under the given stress regime. The pattern when the P/T axes form two distinct sub-clusters is called as the “two-wing” or the “butterfly-wing” pattern (Vavryčuk 2011a). The butterfly wings are well separated provided that friction is high (0.5 or higher). If friction is low, the wings come closer or they overlap.

Fault Instability

Since differently oriented faults have a different susceptibility to be activated and thus being differently unstable in the given stress field, a quantity which measures this instability can be introduced. For example, the fault instability I of all fault orientations can be defined in

the range from 0 to 1 (see Fig. 8) using the following formula (Vavryčuk et al. 2013):

$$I = \frac{\tau - \mu(\sigma - \sigma_1)}{\tau_c - \mu(\sigma_c - \sigma_1)}, \quad (16)$$

where τ_c and σ_c are the shear and effective normal stresses along the principal fault (blue dot in Fig. 6, red dot in Fig. 8), and τ and σ are the shear and effective normal stresses along the analysed fault (black dot in Fig. 8).

Since Eq. 16 is independent of absolute stress values, the fault instability I can be evaluated just from friction μ , shape ratio R ,

$$R = \frac{\sigma_1 - \sigma_2}{\sigma_1 - \sigma_3}, \quad (17)$$

Earthquake Mechanisms and Stress Field, Fig. 8 Definition of the fault instability in the Mohr's diagram. The *red dot* marks the principal fault characterized by instability $I = 1$. The *black dot* marks an arbitrarily

oriented fault with instability I . Quantities τ and σ are the shear and the effective normal stresses, respectively; σ_1 , σ_2 and σ_3 are the effective principal stresses

and from directional cosines $\mathbf{n}$ defining the inclination of the fault plane from the principal stress axes (i.e., $\mathbf{n}$ being expressed in the coordinate system of the principal stress directions). If the reduced stress tensor is scaled as follows:

$$\sigma_1 = 1, \sigma_2 = 1 - 2R, \sigma_3 = -1, \quad (18)$$

where positive values mean compression, stresses τ_c and σ_c along the principal fault read

$$\tau_c = \frac{1}{\sqrt{1 + \mu^2}}, \sigma_c = -\frac{\mu}{\sqrt{1 + \mu^2}}, \quad (19)$$

and consequently

$$I = \frac{\tau - \mu(\sigma - 1)}{\mu + \sqrt{1 + \mu^2}}, \quad (20)$$

where

$$\sigma = n_1^2 + (1 - 2R)n_2^2 - n_3^2,$$

$$\tau = \sqrt{n_1^2 + (1 - 2R)^2 n_2^2 + n_3^2 - (n_1^2 + (1 - 2R)n_2^2 - n_3^2)^2}. \quad (21)$$

The fault instability can be calculated using Eqs. 20 and 21 for all orientations of fault planes and projected into the focal sphere (see Fig. 9). Such figure is, in particular, helpful when analysing

Earthquake Mechanisms and Stress Field, Fig. 9 The fault instability is shown for all possible fault normals; it is colour-scaled and ranges between 0 (the most stable plane) and 1 (the most unstable plane). The lower-hemisphere equal-area projection is used. Directions of the σ_1 , σ_2 and σ_3 axes are (azimuth/plunge): $146^\circ/48^\circ$, $327^\circ/42^\circ$ and $237^\circ/1^\circ$. The shape ratio R is 0.80 and the fault friction μ is 0.5 (Modified after Vavryčuk et al. (2013))

orientations of unstable faults under stress field with inclined principal stress directions.

Principal Focal Mechanisms

As mentioned above, the higher the instability, the higher the probability of the fault being activated. Obviously, a prominent fault plane is the

Earthquake Mechanisms and Stress Field,

Fig. 10 Principal focal mechanisms. (a) Full Mohr's circle diagram, (b) principal nodal lines and P/T axes, and (c, d) principal focal mechanisms. The blue dot in (a) marks the principal fault plane, the arrows in (c) and (d) denote the nodal lines corresponding to the principal fault plane. Point B in (c) and (d) denotes the neutral axis, N denotes north (After Vavryčuk (2011a))

principal fault (Vavryčuk 2011a). This plane is optimally oriented in the stress field and has the highest instability $I = 1$ (see Figs. 6 and 8). Each stress allows for the existence of two distinct principal faults and two distinct principal focal mechanisms (Fig. 10). The reason for the existence of two principal mechanisms is the same as for observing the two-wing pattern of the failure curves and two clusters of focal mechanisms – one principal fault lying in the upper half-plane and the other principal fault in the lower half-plane of the Mohr's circle diagram. The P/T axes of the principal focal mechanisms lie within the two P/T butterfly wings. If the area of unstable faults (see Fig. 6) is decreased, for example, by decreasing pore pressure, the wings become smaller being shrunk to the P/T axes of the principal focal mechanisms in the limit.

The orientation of the principal fault planes and principal focal mechanisms depends on stress and fault friction. The B (neutral) axes of both principal focal mechanisms coincide with the σ_2 axis (Fig. 10b). The P/T axes lie in the σ_1 – σ_3 plane: the σ_1 axis is in the centre between the two P axes, and the σ_3 axis is in the centre between the two T axes. The principal fault planes are those nodal planes whose deviation from the σ_1 axis is less than 45° . Deviation θ between the two principal fault planes is expressed by a formula similar to that for the 2-D stress:

$$\mu^{-1} = \tan 2\theta. \quad (22)$$

Since the relation between the principal focal mechanisms and the orientation of stress is

simple, the inversion for stress orientation from principal focal mechanisms is straightforward. On the other hand, the shape ratio cannot be retrieved from the principal focal mechanisms. The shape ratio constrains the mutual relation between the size and shape of the P and T butterfly wings. Therefore, a rather large set of focal mechanisms is needed to map the wings accurately. Methods for inversion of stress including the shape ratio from a set of focal mechanisms are described below.

Inversion for Stress From Earthquake Mechanisms

Several methods have been proposed for the determination of stress from a set of focal mechanisms of earthquakes (Maury et al. 2013). These methods usually assume that (1) tectonic stress is uniform (homogeneous) in the region, (2) earthquakes occur on pre-existing faults with varying orientations, (3) the slip vector points in the direction of shear stress on the fault (the so-called Wallace-Bott hypothesis; see, Wallace 1951; Bott 1959), and (4) the earthquakes do not interact with each other and do not disturb the background tectonic stress. Obviously, these conditions might not be always satisfied. Firstly, in case that stress is not uniform, the area should be subdivided into smaller areas in which the condition of uniform tectonic stress is reasonable to assume. Secondly, if a high variety of focal mechanisms is not observed, the inversion yields less accurate results. The smaller variety of the observed focal mechanisms, the larger uncertainty in the stress orientations retrieved. Thirdly, the Wallace-Bott assumption of the slip vector parallel to the stress on the fault is valid only in isotropic media. In anisotropic media, both vectors need not be parallel and the problem becomes more involved, particularly, if anisotropy in the focal zone is not known. Finally, stress changes due to the occurrence of small earthquakes are usually negligible but large earthquakes can significantly affect the

background stress field. In this case, inverting for stress should be performed from earthquakes clustered not only in space but also in time and periods between and after a large earthquake should be distinguished.

If the above-mentioned assumptions are reasonably satisfied, the stress inversion methods are capable to determine four parameters of the stress tensor: three angles defining the directions of the principal stress directions, σ_1 , σ_2 and σ_3 , and shape ratio R . The methods are unable to recover the remaining two parameters of the stress tensor. Therefore, the stress tensor is usually searched with the normalized maximum compressive stress

$$\sigma_1 = +1, \quad (23)$$

and with the zero trace

$$Tr(\boldsymbol{\tau}) = \sigma_1 + \sigma_2 + \sigma_3 = 0. \quad (24)$$

This implies that no information about pore pressure, which is isotropic, can be gained from the focal mechanisms.

Next, the individual approaches to stress inversion are described and their pros and cons are mentioned.

Michael Method

A simplest approach to stress inversion is the method of Michael (1984). This method employs Eq. 4 expressed in the following form:

$$\tau_{kj}n_j(\delta_{ik} - n_in_k) = \tau N_i. \quad (25)$$

In order to be able to evaluate the right-hand side of the equation, Michael (1984) applies the Wallace-Bott assumption that direction $\mathbf{N}$ of shear stress component of traction $\mathbf{T}$ on a fault is identical with the slip direction $\mathbf{s}$, and he further assumes that shear stress τ on activated faults has the same value for all studied earthquakes. Since the method cannot determine absolute stress values, τ in Eq. 25 is assumed to be 1 and

Eq. 23 is not applied. Subsequently, Eq. 25 is expressed in the matrix form

$$\mathbf{A}\mathbf{t} = \mathbf{s}, \quad (26)$$

where $\mathbf{t}$ is the vector of stress components

$$\mathbf{t} = [\tau_{11} \quad \tau_{12} \quad \tau_{13} \quad \tau_{22} \quad \tau_{23}]^T, \quad (27)$$

$\mathbf{A}$ is the 3×5 matrix calculated from fault normal $\mathbf{n}$,

$$\begin{bmatrix} n_1(n_2^2 + 2n_3^2) & n_2(1 - 2n_1^2) & n_3(1 - 2n_1^2) & n_1(-n_2^2 + n_3^2) & -2n_1n_2n_3 \\ n_2(-n_1^2 + n_3^2) & n_1(1 - 2n_2^2) & -2n_1n_2n_3 & n_2(n_1^2 + 2n_3^2) & n_3(1 - 2n_2^2) \\ n_3(-2n_1^2 - n_2^2) & -2n_1n_2n_3 & n_1(1 - 2n_3^2) & n_3(-n_1^2 - 2n_2^2) & n_2(1 - 2n_3^2) \end{bmatrix}, \quad (28)$$

and $\mathbf{s}$ is the unit direction of the slip vector. Extending Eq. 28 for focal mechanisms of K earthquakes with known fault normals $\mathbf{n}$ and slip directions $\mathbf{s}$, a system of $3 \times K$ linear equations for five unknown components of stress tensor is obtained. The system is solved using the generalized linear inversion in the L2-norm (Lay and Wallace 1995, their Section 6.4)

$$\mathbf{t} = \mathbf{A}^{-g}\mathbf{s}. \quad (29)$$

The basic drawback of this method is the necessity to know orientations of the faults. Usually, when determining the focal mechanisms, orientations of the two nodal planes are calculated: one nodal plane corresponding to the fault and the other nodal plane (called the auxiliary plane) defining the slip direction. The inherent ambiguity of focal mechanisms does not allow distinguishing easily which of the nodal planes is the fault. If the Michael's method is used with incorrect orientations of the fault planes, the accuracy of the retrieved stress tensor is decreased. On the other hand, the method is quite fast and it can be run repeatedly. Therefore, the confidence regions of the solution are determined using the standard bootstrap method (Michael 1987). If the orientation of fault planes in the focal mechanisms is unknown, each nodal plane has a 50 % probability of being chosen during the bootstrap resampling.

Recently, Vavryčuk (2014) modified the Michael's method and removed the difficulty with the unknown fault orientations. He proposed inverting jointly for stress and for the

fault orientations by applying the fault instability constraint. According to this constraint, the fault is identified with that nodal plane which has a higher value of instability calculated using Eq. 20. The stress is calculated in iterations and overall friction μ on faults is also determined. Numerical tests show that the iterative stress inversion is fast and accurate and performs better than the standard Michael's inversion.

Angelier Method

The difficulty with determining the fault plane in the focal mechanisms is also overcome in the method developed by Angelier (2002). This method is based on maximizing the slip shear stress component (SSSC) along the fault

$$\tau_s = T_i s_i = \tau_{ij} n_i s_j. \quad (30)$$

Since the SSSC value is symmetric with respect to vectors $\mathbf{n}$ and $\mathbf{s}$, it is invariant of the choice of the fault plane from the two nodal planes. The condition of the maximum shear stress Eq. 30 is not fully correct and physically means that faults should obey the so-called Tresca failure criterion where faults are assumed to have zero friction. Only faults with zero friction can achieve maximum shear stress and satisfy Eq. 30; for faults with friction, the SSSC value is always reduced (see Fig. 11).

For K focal mechanisms, the total SSSC value is maximized as follows:

Earthquake Mechanisms and Stress Field, Fig. 11 Tresca and Mohr-Coulomb failure criteria. The Tresca failure criterion is unphysical and corresponds to a fault with zero friction. The red dot marks the principal fault plane

$$\tau_s^{\text{total}} = \frac{\tau_{ij}}{\tau_{\text{max}}} \sum_{k=1}^K n_i^{(k)} s_j^{(k)}, \quad (31)$$

where

$$\tau_{\text{max}} = \frac{\sigma_1 - \sigma_3}{2}. \quad (32)$$

and the optimum stress tensor is calculated analytically (see Angelier 2002). An alternative approach defines the total SSSC value in the form:

$$\tau_s^{\text{total}} = \tau_{ij} \sum_{k=1}^K n_i^{(k)} s_j^{(k)}, \quad (33)$$

with the normalization condition

$$\sigma_1^2 + \sigma_2^2 + \sigma_3^2 = 1. \quad (34)$$

and with the zero trace condition Eq. 24. In this case, the inversion for the optimum stress tensor can be performed using a grid search through the principal stress directions and shape ratio R . The fit function is maximized in the L1-norm.

Although the condition of maximizing the SSSC value looks as a rather rough approximation, its use in practice is advocated by Angelier (2002) for the following reasons. Firstly, the activated fault planes are located mostly close to the top of the Mohr's circle diagram. For example, friction of

0.6 reduces the maximum shear stress by 13 % only. Secondly, numerical tests show that if focal mechanisms inverted display a sufficient variety, maximizing the SSSC value leads to a small bias in the retrieved stress directions. Thirdly, maximizing the SSSC value is quite robust with respect to the errors present in focal mechanisms.

Gephart and Forsyth Method

Another way how to solve the problem with ambiguous fault plane orientations in stress inversions is proposed by Gephart and Forsyth (1984). The method is based on minimizing the deviation between direction $\mathbf{N}$ of shear stress and slip direction $\mathbf{s}$ along the fault. This deviation is calculated for both options of the fault orientation and the lower value enters into the total sum over all K focal mechanisms minimized during the inversion:

$$S = \sum_{k=1}^K \text{acos}(\mathbf{N}^{(k)} \cdot \mathbf{s}^{(k)}). \quad (35)$$

The method was further modified and improved by Lund and Slunga (1999) who applied a more physical criterion for identifying the true fault planes. The criterion is based on the evaluation of instability of the fault using Eq. 20 and the fault plane is identified with that nodal plane which is more unstable and thus more susceptible to failure under the given stress field. The misfit function is minimized in the L1-norm by using

Earthquake Mechanisms and Stress Field,

Fig. 12 Example of data used in numerical tests of stress inversions. The plots show 200 noise-free focal mechanisms selected to satisfy the Mohr-Coulomb failure criterion. *Left/right* plots – dataset with a full/reduced variety of focal mechanisms. (a, b) Mohr's circle diagrams, (c, d) P/T axes and (e, f) corresponding nodal lines. The P axes are marked by the red circles and T axes by the blue crosses in (c) and (d). The σ_1 , σ_2 and σ_3 stress axes are (azimuth/plunge): $115^\circ/65^\circ$, $228^\circ/10^\circ$ and $322^\circ/23^\circ$, respectively. Shape ratio R is 0.70, cohesion C is 0.85, pore pressure p is zero and friction μ is 0.60. The minimum instability of faults is 0.82

the robust grid search inversion scheme. It is also possible to exclude a predefined number of outliers from the misfit function the result of the inversion to be less sensitive to large errors in input data. Since the misfit function is usually smooth and simple, the time-consuming grid search can be substituted by any non-linear inversion method. For example, the gradient or simplex methods can be applied with a success. This applies also to the Angelier method defined by Eqs. 33 and 34.

Accuracy of Stress Inversion Algorithms: Numerical Tests

The robustness and accuracy of the stress inversion methods can be efficiently tested using numerical modelling. The key parameters of

any stress inversion are the number of focal mechanisms inverted, their accuracy and variability. The inversions yield orientations of the principal stress axes and shape ratio R .

Numerical tests performed with sets of 25–250 focal mechanisms are presented. The stress tensor is fixed for all datasets. The focal mechanisms are selected to satisfy the Mohr-Coulomb failure criterion (see Fig. 12a, b) and subsequently they are used for the calculation of moment tensors. The moment tensors were contaminated by uniform noise ranging from 0 to $\pm 50\%$ of the norm of the moment tensor (calculated as the maximum of absolute values of the moment tensor eigenvalues). The noisy moment tensors were decomposed back into strikes, dips and rakes of noisy focal mechanisms inverted for stress. The deviation between the true and noisy fault normals and slips attained values from 0° to 25°

Earthquake Mechanisms and Stress Field, Fig. 13 Mean deviation of noisy fault normals as a function of noise superimposed on the moment tensors. The deviation is colour-coded and evaluated in degrees. The noisy slip directions display the same deviations

(see Fig. 13). Since the inverted focal mechanisms were calculated from moment tensors, knowledge of the orientation of the fault planes was lost in the data set. The inversion was run repeatedly using 50 realizations of random noise and for two types of sets of focal mechanisms. The first set consisted of focal mechanisms which projected into both half-planes of the Mohr's circle diagram and thus covered both butterfly wings in the P/T plot (see Fig. 12, left plots). The second set consisted of focal mechanisms projected just into upper half-plane of the Mohr's circle diagram and covered just one butterfly wing in the P/T plot (see Fig. 12, right plots). The inverted principal stress directions and shape ratios for both data sets and all realizations of random noise were compared with the true values and the errors were evaluated (see Figs. 14 and 15).

The tests indicate that the accuracy of the stress inversions significantly varies and strongly depends on noise in the data and on the number of focal mechanisms inverted. All inversions yield satisfactory results for the principal stress directions with an average error less than 15° for 25 noisy focal mechanisms inverted (see Fig. 14, left plots). If a reduced variety of focal mechanisms was used (see Fig. 15, left plots), the method of Angelier (2002) produced

systematically worse results than the other methods. The errors occurred even in the case of 250 noise-free focal mechanisms. Slightly biased results for noise-free data were produced also by the method of Michael (1984), because this method is sensitive to the ambiguity in the orientation of fault planes.

In addition, the tests reveal that the shape ratio is a more critical parameter than the orientation of the principal stress directions (see Figs. 14 and 15, right plots). The method of Angelier (2002) completely failed even when the high number of noise-free focal mechanisms of the full variety were inverted (see Fig. 14) yielding the shape ratio of about 0.5 instead of 0.7. Also the method of Michael (1984) works significantly worse than the method of Gephart and Forsyth (1984) and its modification proposed by Lund and Slunga (1999). The latter two methods produce results of similar accuracy, the method of Lund and Slunga (1999) working slightly better and being less sensitive to the low number of focal mechanisms, high noise in the data and the limited variability of focal mechanisms (see Fig. 15, right plots).

Inversion for Temporal or Spatial Variation of Stress

With an increasing number and accuracy of focal mechanisms of earthquakes occurring in seismically active regions, it becomes possible to study spatial variations of stress or its temporal evolution. The simplest approach how to study the spatial variation of stress is to subdivide the study area into subareas or cells of a similar stress regime and invert for stress of individual cells. Similarly, in case of the time evolution of stress, the total time period of observations can be split into several phases of the seismic activity and stress can be inverted for individual time windows. In order to increase the number of focal mechanisms inverted, the individual cells or time windows can partly overlap. This produces smooth results highlighting their large-scale lateral variations or long-period trends being very analogous to the moving average method.

Earthquake Mechanisms and Stress Field, Fig. 14 Mean error of principal stress directions (*left*) and of the shape ratio (*right*) as a function of the number of inverted focal mechanisms and noise in moment tensors. The data set with the full variety of focal mechanisms (two-wings data) is inverted. The errors are shown for

the method of Michael (1984), Angelier (2002), Gephart and Forsyth (1984) and Lund and Slunga (1999). The method of Angelier (2002) employs Eqs. 33 and 34. The errors are calculated from 50 random realizations of noise. The errors in the stress directions are in degrees, the errors in the shape ratio are in percent

Earthquake Mechanisms and Stress Field, Fig. 15 The same as for Fig. 14, but for the data set with the reduced variety of focal mechanisms (one-wing data)

The mentioned stress inversions can be exemplified on several applications. The simplest approach, when the area under study is subdivided just into two subareas of different

stress regimes, was presented, for example, by Vavryčuk (2006) for deep earthquakes in the Tonga subducting slab (see Fig. 16). The slab is considerably deformed at depths between

Earthquake Mechanisms and Stress Field, Fig. 16 Inversion for stress in the Tonga subduction zone. *Left plot* – the map view with epicentres of earthquakes. *Green dots* mark earthquake foci at depths between 100 and 500 km, *blue/red dots* mark deep-focus earthquakes at depths greater than 500 km in the northern/southern cluster. The *grey arrows* show the horizontal projections of the maximum compression in the northern/southern cluster. *Middle plots* – P axes (*circles*) and T axes

(*plus signs*) of focal mechanisms distributed over the focal sphere for earthquakes from the northern (*upper plot*) and southern (*lower plot*) slab segments. *Right plots* – the misfit function for the principal stress axis σ_1 , defined as the average deviation (in degrees) between the predicted shear stress directions and the observed slips at the faults. The Gephart and Forsyth inversion method (1984) was applied. The optimum directions of the principal stresses are marked by *circles* (Modified after Vavříček (2006))

500 and 670 km and can be subdivided into two segments of different orientations characterized by different principal stress directions. The stress inversion shows that the maximum compressive stress is directed along the down-dip motion of the slab in both segments. A more detailed mapping of lateral variations of stress obtained from focal mechanisms was published by Hardebeck (2006) for Southern California who employed the stress inversion code SATSI developed by Hardebeck and Michael (2006). This code inverts simultaneously for stress in all subareas of the region under study and minimizes the difference in stress between adjacent subareas to suppress over fitting of noisy data (see Fig. 17). A modification of this code, called MSATSI and working in the Matlab environment, was applied by Ickrath et al. (2014) to analyse spatial and temporal variations of stress prior and after the 1999 Mw 7.4 Izmit earthquake in Turkey. This analysis

revealed systematic rotations of stress related to the occurrence of the Izmit earthquake. The rotation of the principal stress directions have been observed also after the 1999 Mw 7.6 Chi-Chi earthquake in Taiwan (Wu et al. 2010) and for the 2011 Mw 9 Tohoku-oki earthquake in Japan (Yang et al. 2013). Spatial and temporal variations of stress from focal mechanisms have been studied also for New Zealand (Townend et al. 2012) with focus on the 2010 Mw 6.2 Christchurch earthquake, and for other seismically active regions including geothermal fields in which seismicity is induced by fluid injections (Martínez-Garzón et al. 2013).

Summary

The stress field and fracture processes in the Earth's crust are closely related phenomena.

Earthquake Mechanisms and Stress Field,

Fig. 17 Stress inversion for southern California.

A data set of 6957 focal mechanisms is inverted for the stress tensor at points on a 0.1° grid. The bar orientation shows the direction of the maximum horizontal stress axis, and the shading of the bar indicates the stress regime, following Simpson (1997).

Light grey lines show mapped fault traces, and the black line shows the San Andreas Fault. The damped inversion method of Hardebeck and Michael (2006) is used with damping parameter $e = 1$ (After Hardebeck and Michael (2006), their figure 5c)

Fracturing is controlled by shear stress on the fault, pore-fluid pressure, cohesion and fault friction. In addition, the orientation of the fault with respect to the principal stress directions governs susceptibility of the fault to be ruptured. An essential role in the stress analysis play principal faults – the faults which are optimally oriented for shear faulting and thus being the most unstable under the given stress conditions. The type of faulting, the orientation of the activated faults and the direction of the slip along the faults can be inverted for stress and its spatial and temporal variations within the Earth's crust. The stress inversions work best if the fault orientations are known. If the fault plane cannot be uniquely identified from the focal mechanisms, the inversions are less accurate. The inversions are capable to retrieve four stress parameters: the principal stress directions and the shape ratio. The accuracy of the results depends on the applied inversion method, on the number of inverted focal mechanisms, their errors and variety. The most critical parameter is the shape ratio, which

can be successfully recovered only by the Gephart and Forsyth (1984), Lund and Slunga (1999) and Vavryčuk (2014) methods provided that a high number of accurate focal mechanisms is available.

Introduction

Seismology has played a key role in the development of the plate tectonic theory, which describes and explains the motions of lithosphere plates. The global distribution of earthquakes outlines the plate boundaries, the occurrence of deep earthquakes indicates regions where plates are recycled back into Earth's mantle, and earthquake fault plane solutions provide information about the relative sense of motion at plate boundaries.

Three different types of plate boundaries exist: convergent, divergent, and transform. Relative motion of two plates toward each other occurs at convergent, away from each other at divergent, and parallel to the boundary at transform boundaries (Fig. 1). Convergent plate boundaries are subduction zones where oceanic lithosphere of one plate dives beneath another plate. The overriding plate can be either oceanic lithosphere, such as in the Philippine Sea, or continental lithosphere, such as in South America. Continental collision zones are another form of convergent boundary. Continental lithosphere material, in

particular continental crust, is not dense enough to sink into the asthenosphere and where two continents collide, such as in the Himalayas where the Indian plate is actively colliding with the Eurasian plate, compressional mountain belts are formed. Divergent plate boundaries in the ocean are mid-ocean ridge spreading centers where new oceanic lithosphere is generated. The Mid-Atlantic Ridge and the East Pacific Rise are examples. Mature divergent plate boundaries are always associated with seafloor spreading; divergent plate boundaries in continents, such as the East African Rift System, indicate rift initiation, young or failed rifting. At transform plate boundaries, new material is neither created nor destructed, rather two plates move sideways (laterally) past each other. The motion sense along a transform fault can be either right lateral (dextral) or left lateral (sinistral). The best-known transform plate boundaries occur on continents, e.g., the San Andreas Fault in California where the North American and Pacific plates slide past each other in a right-lateral sense. Transform faults are also abundant in oceanic lithosphere where they often connect two spreading segments.

Most earthquakes occur at the boundary between two tectonic plates. These are interplate earthquakes. Fewer earthquakes occur inside plates, and these are intraplate earthquakes.

The depth of earthquakes within the lithosphere is usually restricted to the shallow part of the lithosphere that deforms in a brittle fashion. In the continental crust, the depth cutoff is often associated with the 350 °C isotherm which is reached at mid-crustal depth; the actual cutoff depth (between about 10 and 25 km) depends on the temperature gradient. At temperatures above 350 °C, the bulk material of continental crust deforms in a ductile, plastic fashion. In the oceanic lithosphere, due to different mineral composition, ductile deformation sets in above about 600 °C, which, in oceanic lithosphere, is usually reached in the uppermost mantle (the depth depends on lithosphere cooling and can be estimated using a simply half-space cooling model). Some examples exist where earthquakes occur in the lower crust or uppermost mantle of continental lithosphere, such as in parts of the East African Rift System and of the Tibetan Plateau. Some researchers suggest that these events are located in the uppermost mantle, which, at about the same depth and temperature, is stronger than crustal material, while others argue that under certain circumstances earthquakes can occur throughout the continental crust; this is a topic of active research. Deep earthquakes within the oceanic lithosphere of subducting plates are another exception; they are discussed below.

The source mechanisms (also called fault plane solutions and focal mechanisms or, using a more general description, seismic moment tensors) of tectonic earthquakes are generally due to shear faulting on a fault plane. In the moment tensor description, this is a pure double-couple source, i.e., no volume change or other non-shear components (such as a compensated linear vector dipole) are present at the source. The earthquake mechanisms that correspond to extension, compression, and lateral motion are normal, thrust (reverse), and strike-slip fault plane solutions; basic examples are shown in Fig. 1. Normal faults strike perpendicular to the extension direction, and fault dips commonly found from the analysis

of earthquake data are in the 30°–60° range. Thrust (reverse) faults strike perpendicular to the convergence directions and often have a shallow-dip angle (<30°); this is typical for megathrust subduction zone earthquakes. Transform faults are oriented parallel to the relative motion direction and have right- or left-lateral strike-slip mechanisms with near-vertical fault planes. Earthquake slip vectors describe the relative motion of two fault surfaces relative to each other. They have been used extensively in the past to estimate relative plate motion directions; however, we know now that spreading directions and slip on subduction zone thrust earthquakes are not necessarily parallel to plate motion directions.

Earthquake fault plane solutions provide an overall, average description of the seismic source effectively treating it as a point source. Effects of slip on a finite fault or complex ruptures involving several faults or fault segments are observed seismically and in the field. However, these topics are not addressed in this entry.

Plate boundaries in oceanic lithosphere are often narrower and simpler than in continental lithosphere. They will be discussed first with Fig. 2 showing a simple conceptual model.

Mid-Ocean Ridges and Oceanic Transform Faults

New oceanic lithosphere at mid-ocean ridge spreading centers is due to extrusive and intrusive volcanism. The extensional nature of spreading is reflected in the observed normal-faulting earthquake mechanisms. Figure 3 shows the global distribution of spreading ridges and the normal-faulting mechanisms of larger (moment magnitude M_w about 5 and larger) earthquakes along them. The mechanisms have nodal planes parallel to the ridge axes.

By design, Fig. 3 shows the distribution of $M \geq 5$ earthquakes along the global ridge system. Most of these events occur along ridges with slow (≤ 55 mm/year) spreading rates. Few normal-faulting earthquakes on ridges exceed $M_w = 6$ and the largest event, which occurred

Earthquake Mechanisms and Tectonics,

Fig. 2 Earthquake mechanisms in oceanic environments. Earthquakes occur mainly on active faults (*double line*: spreading center; *single line*: transform fault; *barbed line*: subduction zone, barbs point in direction of subducting plate). *Dashed line* is an inactive fracture zone. *Arrows* show relative motion sense

along the ultraslow (≤ 20 mm/year) Gakkel Ridge separating the North American and Eurasian plates in the Arctic region, reached only $M_w = 6.4$ (Table 1). Maximum earthquake size and the frequency of large earthquake occurrence are related to spreading rate. Note the continuous band of earthquake mechanisms along the slow-spreading Mid-Atlantic and Central and Southwest Indian ridges and the lack of events along the fast-spreading (here set as 80 mm/year and faster) ridges south of Australia and the East Pacific Rise. Along the East Pacific Rise, normal-faulting earthquakes rarely exceed $M = 5$. Differences between slow- and fast-spreading ridges are due to the thermal structure of the lithosphere.

Microearthquake activity along the entire ridge system – particularly along fast-spreading ridges – is probably vigorous based on observations from still relatively few, temporary seismic observations from the ocean floor. Even after considering smaller earthquakes, the seismic moment released by all earthquakes along the

ridges accounts for only a small percentage of the relative plate motions indicating the importance of aseismic slip.

The mid-ocean ridge segments are connected to each other by oceanic transform faults. Ridge-transform intersections are often nearly perpendicular. Motion along transforms is lateral and parallel to relative plate motion directions. Transforms offset ridge segments, and the offset direction (i.e., whether the next segment is to the right or left) determines motion sense and thus whether a fault is right lateral or left lateral (Fig. 2). The offset-parallel nodal plane is usually the fault plane, and both nodal planes are usually near vertical. Parts of a transform fault not between two ridge segments become seismically inactive and are called fracture zone. The Mendocino fracture zone, extending halfway across the northeast Pacific Ocean, is a famous example; its active transform fault part is only about 200 km long and connects a spreading ridge with the Mendocino triple junction in northern California.

Earthquake Mechanisms and Tectonics, Fig. 4 Global distribution of oceanic transform faults (heavy lines) and oceanic strike-slip focal mechanisms (beach balls) for 1977–1998 from the Global CMT

project. Note earthquakes occur along almost all transforms independent of plate motion rate (From Bird et al. 2002) from AGU publications

The global distribution of oceanic transform faults and oceanic transform earthquakes ($M_w \geq 5$) shows these strike-slip earthquakes occur along all oceanic transform faults independent of motion rate (Fig. 4). However, the size of the largest earthquake along an oceanic transform fault decreases with increase in plate motion rate. This is due to the thermal structure of the lithosphere. The thin seismogenic part of the lithosphere (above 600 °C) limits the maximum fault area and thus the maximum size to about $M_w = 7-7.5$. Some of the largest ridge-to-ridge strike-slip earthquakes have been observed along the Romanche transform in the equatorial Mid-Atlantic (Table 1). Global studies indicate that earthquakes account for only part of the predicted plate motions along most oceanic transform faults, requiring, as along spreading ridges, significant aseismic slip. How the seismic slip deficit is accommodated, whether as fully seismic patches imbedded in creeping fault patches or as faults that alternate between seismic and aseismic slip, is a matter of current research.

Subduction Zones

The largest earthquakes on Earth are shallow-depth megathrust earthquakes at plate interfaces of subduction zones. The complex mechanics of subduction, though, generates strong earthquakes also away from the plate interface: (i) As the down-going plate approaches a subduction trench, the plate has to bend from a horizontal to an inclined direction generating bending stresses. (ii) Earthquakes occur within the overriding plate near plate interfaces. (iii) Within the cold subducting slab, earthquakes can occur at greater depth than elsewhere. Cases (i) to (iii) are intraplate earthquakes that occur within the overriding or the subducting plate (cf. interplate or plate boundary earthquakes). Figure 5 illustrates earthquake types observed in subduction zones, and Table 1 lists an example for each type. Note that not all types are observed at each subduction zone.

Plate interface earthquakes have thrust mechanisms indicating underthrusting of the

Earthquake Mechanisms and Tectonics, Fig. 5 Schematic overview of some earthquake types observed in subduction zones. Not all event types occur at each subduction zone. Focal mechanisms are in cross-sectional view and are roughly scaled according to maximum observed size. *Arrows* show relative motion sense

for interplate megathrust earthquake and state of stress for intraplate earthquakes (*diverging arrows*, extension; *converging arrows*, compression). Intermediate-deep event is an example for in-plane extension; some plates show in-plane compression throughout the slab (then intermediate and deep mechanisms are the same)

subducting plate beneath the overriding plate along a shallow-dipping fault. They occur landward from the trench (or, in general, beneath the leading edge of the overriding plate). The mechanisms have nodal planes parallel to the strike of the trench (and coast), and slip vectors, which indicate the relative motion sense on the fault, are often subparallel to the relative plate motion directions.

The largest earthquake measured with seismometers is the 1960 Chile ($M_w = 9.5$) subduction zone earthquake. The rupture dimensions corresponding to an earthquake of this size are about 1,000 km rupture length, 200 km down-dip rupture width, and 10–30 m average slip on the entire area that ruptured. Additional infamous examples include the 1964 Alaska ($M_w = 9.2$), the 2004 Sumatra-Andaman ($M_w = 9.1$), and the 2011 Tohoku, Japan ($M_w = 9.0$), earthquakes. Such gigantic earthquakes can be very devastating, and they are often accompanied by large, deadly tsunamis that travel across ocean basins

to cause destruction far away from the earthquake rupture area itself.

As an oceanic plate starts to descend beneath another plate, it has to bend to accommodate the change in plate motion from horizontal to an inclined direction. The bending stresses are largest seaward of the trench at the outer rise and the outer trench slope. The stresses due to bending and slab-pull forces cause earthquakes. Plate bending in the upper part of a subducting lithosphere plate is extensional resulting in normal faulting; such earthquakes are observed at many subduction zones. Bending stresses in the lower part are compressional resulting in thrust faulting; such earthquakes occur less frequently. The depth of transition from extension to compression within a plate is an indicator for the stress state within oceanic lithosphere. T-axes of normal faulting and P-axes of thrust earthquakes are usually pointing in the direction of plate motion with nodal planes subparallel to the strike of the trench system.

The largest normal-faulting earthquakes observed globally are the plate-bending earthquakes seaward of trenches, and they often generate tsunamis. Examples include the 1933 Sanriku, Japan ($M_w = 8.3$), the 1977 Sumbawa, Indonesia ($M_w = 8.3$), and the 2009 Samoa Island ($M_w = 8.1$) events. In several instances modeling of seismologic data has shown that outer rise earthquakes can occur as “doublets” with a shallow normal-faulting sub-event and an almost coincident deeper thrust sub-event reflecting stress changes transmitted through the plate. The December 2012 Honshu, Japan, earthquake seaward of the great 2011 Tohoku earthquake is an example.

Seismicity landward of a trench within the overriding plate is common. The overall tectonic environment is compressional, but within these regions of complex deformation, a variety of earthquake source mechanisms may be observed. Most earthquakes are relatively small because the deforming edge of a plate usually cannot sustain large strains. A potential example for a larger earthquake within the overriding plate is the April 1992 Petrolia earthquake where the main $M_w = 7.2$ thrust earthquake ruptured within the North American plate and above the subducting Gorda plate.

Earthquakes in the subducting slab have been recorded down to about 700 km depth as the cold lithospheric slab penetrates into the mantle and is slowly heated. Temperatures within the slab are significantly lower than in the surrounding mantle, which allows earthquakes to occur within the colder core of the slab at greater depth than anywhere else on Earth.

The mechanisms for generating earthquakes at depths of more than 100 km are not fully understood and are the topic of current research. The observed earthquake source parameters are usually consistent with pure shear dislocations (or fault slip as for shallow earthquakes). However, the normal stresses due to the high confining pressures at depth should actually prohibit shear faulting. Various mechanisms have been presented trying to explain the existence of intermediate (70–300 km depth) and deep (300–700 km depth) earthquakes including

sudden phase changes, breakdown of hydrous minerals, lubrication of fault surfaces by melting of rock, or a combination of these mechanisms.

The earthquake fault plane solutions for deep earthquakes usually show either down-dip extension (T-axis parallel to slab-dip direction) or down-dip compression (P-axis parallel to slab-dip direction). It is thought that deep (300–700 km depth) earthquakes are under compression because the slab is penetrating into stronger material beneath the asthenosphere, which leads to increased subduction resistance. The state of stress for intermediate-deep events (70–300 km depth), however, varies for different subduction zones and can be either under compression or tension. Down-dip compression at intermediate depth could occur if compressive stresses are transmitted from deeper parts of the slab as it encounters strong subduction resistance. Down-dip tension is presumably the result of a slab extending under its own weight as it sinks into less dense surrounding mantle when its leading edge is not experiencing strong subduction resistance. Examples for the former (compressive stresses throughout down-going slab) might be the Tonga and North Honshu subduction zones, while the Kuriles, Chile, and Sunda subduction zones might represent slabs where down-dip tension at intermediate depth and compressive stress at depths of more than 300 km are observed.

The global depth distribution of deep earthquakes (Fig. 6) shows a strong decrease of activity to about 300 km depth, a broad, weak maximum at about 400 km depth, and a significant increase in seismic activity below about 530 km (down to the maximum observed depth of about 700 km). Variations to this general pattern between subduction zones are likely due to differences in slab thermal structure, which depends on relative plate motion rate, age of the subducting plate, and whether the slab is continuous or not. Intermediate-deep earthquakes (70–300 km depth) reach about $M_w = 8$ (Table 1). The largest deep earthquakes occur close to the base of the seismically active part of the slab below 600 km depth and can exceed $M_w = 8$. Examples include the 1994 Bolivia ($M_w = 8.2$) and the 2013 Sea of Okhotsk ($M_w = 8.4$) earthquakes (Table 1).

Earthquake Mechanisms and Tectonics, Fig. 6 Depth versus frequency of earthquake occurrence (*top*) and cumulative seismic moment release (*bottom*) for earthquakes below 100 km depth binned in 10 km steps. See reference for data source. *Left* earthquakes with $M_w < 5.75$ and *right* larger events. Numbers in the *top* are total number of earthquakes shown; vertical axis is

percent of total. Note rapid decay of activity from 150 km to 300 km depth, a small local maxima of events near 400 km, and strong increase below about 530 km depth. Scale at the *bottom* is in units of $\log(M_0)$ dyne cm (subtract 7 for units of [Nm]) (From Estabrook 2004) from AGU publications

Earthquakes in Continental Plate Boundary Settings

Plate boundaries in continental environments are generally more complex and much broader than their oceanic counterparts. This is likely due to differences in crustal thickness, composition, density, and mechanical properties of continental relative to oceanic lithosphere. For example, the low density of continental crust prevents it from subducting and causes mountain building when two continental lithosphere plates collide such as the India-Eurasia collision, which is forming the Himalayan Mountains.

Continental plate boundary zones include convergent, divergent, and transform boundaries. The earthquake focal mechanisms within each zone follow their oceanic counterparts with thrust faulting in convergent, normal faulting in divergent, and strike-slip faulting in transform settings.

The Alpine-Himalayan belt is an example of a large-scale zone of (primarily) continental collision that stretches from the Gibraltar Arc in the west to Southeast Asia in the east. Along this belt, the Eurasian plate collides with the African (Nubian), Arabian, and Indian plates. The seismic deformation is released primarily by thrust-faulting earthquakes with slip vectors that are usually subparallel to the plate motion direction. Large, destructive thrust-faulting earthquakes, for example, are observed in the Caucasus

Mountains (such as the 1988 Spitak, Armenia, earthquake) and within a wide fold-and-thrust belt of the Zagros Mountains, Iran. Underthrusting of the Indian plate beneath Eurasia along the Himalayan front has generated some great (magnitude $M \geq 8$) earthquakes such as the 1934 Bihar-Nepal, India, earthquake ($M_w = 8.1$, Table 1), and possibly even larger earthquakes may have occurred in historic times.

Continental lithosphere is less dense than upper mantle and does not subduct resulting in the absence of deep earthquakes in continental collision zones. However, intermediate-deep earthquakes in the Hindu Kush region and the Vrancea zone of Romania (such as the destructive 1977 Bucharest earthquake) as well as infrequent deep earthquakes beneath southern Spain (such as the 2010 $M_w = 6.4$ earthquake) occur within the Alpine-Himalayan belt. These earthquakes are the result of past subduction of oceanic lithosphere, and their mechanisms are as expected in subduction zones (i.e., P- or T-axis subparallel to presumed slab-dip direction where known).

A consequence of the absence of a subducting slab in continent-continent collision, in addition to mountain building, is the lateral motion or “escape” of large crustal blocks. This is observed, for example, in the India-Eurasia collision as eastward escape of the over-thickened Tibetan Plateau. Deformation is accommodated along left-lateral strike-slip faults (e.g., Altyn Tagh and Kunlun faults) at the northern boundary of

the plateau and as east–west-oriented extension along north–south trending grabens internal to the plateau. Examples for large earthquakes include the 2001 $M_w = 7.8$ strike-slip event on the Kunlun Fault in northern Tibet (Table 1) and the 2008 $M_w = 7.1$ event in northern Tibet, which is one of the largest continental normal-faulting earthquakes in recent years. As crustal material is extruded toward east, it encounters resistance from the stable South China Block resulting in compression at the eastern edge of the Tibetan Plateau that is released in earthquakes. An example is the destructive 2008 $M_w = 7.9$ Sichuan, China, earthquake that occurred on the northeast trending Longmenshan thrust fault.

A similar situation is encountered at the Arabia-Eurasia collision zone where the Anatolian Block, bounded by the left-lateral East Anatolian Fault at the southeast and the right-lateral North Anatolian Fault at the north, is escaping westward as the Arabian plate bulldozes into Eurasia generating the Caucasus Mountains. The destructive 1999 $M_w = 7.4$ Izmit, Turkey, earthquake is an example of activity on the North Anatolian Fault. The Anatolian Block has room to escape westward because the Aegean Sea is a weak region of active back-arc extension behind the southward retreating Hellenic subduction zone. Extension in the Aegean Sea and in westernmost Anatolia is subparallel to the convergence direction, which for the most part is roughly north–south oriented. The 1970 $M_w = 7.1$ Gediz, Turkey, earthquake is a normal-faulting example (Table 1). The broad region of extension in the Basin and Range province of the western United States perhaps represents similar tectonics landwards (east) of the North American plate boundary.

The East African Rift System is an example for a large-scale zone of continental extension where two lithospheric plates slowly spread apart (at about 5 mm/year). The earthquake distribution is broader than at mid-ocean ridges, and the rift actually splits into an eastern and western branch when it encounters the relatively strong and deep-rooted Tanzanian Craton. Earthquakes have normal-faulting mechanisms with strikes parallel to the direction of the East African Rift

as expected. Unusually deep normal-faulting earthquakes, either in the lowermost crust or in the uppermost mantle, has been observed in some parts where the rift is proximal to the cold craton; their origin and exact location relative to the crust-mantle boundary are research topics. Infrequent but rather strong normal-faulting earthquakes seem to occur in the least developed and most slowly spreading southern part of the rift such as the 2006 $M_w = 7.0$ Mozambique earthquake. The rift could eventually develop into an oceanic spreading center and produce new oceanic crust. The geologic record, however, shows that not all continental rifts evolve into oceanic spreading centers and may simply die such as the failed Midcontinental Rift System in the south-central part of the North American plate.

The Pacific-North America plate boundary in the western United States is an example of a continental transform plate boundary. The right-lateral San Andreas Fault takes up most relative plate motion, while the remainder is distributed over faults subparallel to the San Andreas Fault within a wide plate boundary zone. The boundary is wider than observed in oceanic settings. The largest historic earthquakes along the San Andreas Fault are the 1906 $M_w = 7.8$ San Francisco and the 1857 $M_w = 7.9$ Fort Tejon earthquakes rupturing the northern and the central-southern segment of the fault, respectively.

Intraplate Earthquakes

Most earthquakes occur at (narrow or broad) plate boundaries. However, earthquakes are observed to occur within plates far from any boundary. These earthquakes show the limits of plate rigidity and indicate plate internal deformation. Intraplate stresses causing the earthquakes are thought to be transmitted from the plate boundaries or to originate from addition (mountains) or removal (melting glaciers) of internal loads accompanied by the viscoelastic response of the lithosphere. It is assumed that intraplate earthquakes mainly reactivate preexisting faults or occur in zones of preexisting crustal weakness.

Away from plate boundaries, loading (stressing) rates are low and intraplate earthquakes consequently should occur less frequently than plate boundaries events – their recurrence intervals should be longer.

Seismicity in the New Madrid, Missouri, area seems to utilize zones of weakness that were originally generated by the Precambrian failed Midcontinent Rift System. Three $M_w \geq 7.5$ earthquakes occurred in the area in 1811–1812. The source mechanisms are not directly known but probably involved strike-slip and thrust motions on several faults.

Source mechanisms of intraplate earthquakes can be normal, thrust, or strike-slip depending on the stresses inside the lithosphere plate. As such, intraplate source mechanisms are indicators of the stress field, and their analysis is one of the main tools available to estimate stresses in the crust. In many regions, such as North America, internal stresses are compressional, and most earthquakes have thrust and strike-slip source mechanisms. The 2001 $M_w = 7.6$ Gujarat, India, earthquake (Table 1) is an example of intraplate thrust faulting that is probably a consequence of collisional plate boundary forces that are exerted several hundred kilometers away from the epicenter. A counterexample is the European Cenozoic Rift System in the foreland of the Alps that formed in response to the Alpine orogeny; most earthquakes north of the Alps have either normal or strike-slip mechanisms. Intraplate regions pose a challenge to earthquake preparedness because large, potentially destructive earthquakes occur very infrequently (on the order of thousand years or more) but could possibly occur almost anywhere within a plate.

Intraplate earthquakes also occur in oceanic plates. In many cases these earthquakes are located along the inactive fracture zones of transform fault systems or relatively close to the oceanic ridge-transform system. The former are possibly caused by stresses due to differential cooling on either side of a fracture zone, and mechanisms are either strike-slip or vertical dip-slip (one nodal plane is vertical with up or down motion along it). The latter likely represent local stress field variations due to formation of

new oceanic crust, cooling of oceanic lithosphere, and geometrical complexities in plate motions; observed focal solutions include normal, thrust, and strike-slip mechanisms. These earthquakes are usually not very large.

A different type of oceanic intraplate earthquakes is possibly associated with initial formation of new oceanic plate boundaries. The largest strike-slip earthquake ever recorded ($M_w = 8.6$, Table 1) occurred in April 2012 in the Indian Ocean a few hundred kilometers off the west coast of northern Sumatra, Indonesia. The epicenter is located in a broad zone of deformation that marks the diffuse India-Australia plate boundary. Plate boundary faults are not (yet) developed and the stresses due to the slow relative plate motion causes ruptures along zones of preexisting weakness such as fracture zones. The 2012 sequence (including a $M_w = 8.2$ aftershock) shows a complex rupture pattern involving ruptures on several faults. The 1998 $M_w = 8.1$ earthquake near the Balleny Islands, which occurred a few hundred kilometers from the Australia-Antarctic plate boundary, also showed complex faulting behavior and may represent a similar case of reactivation or rupturing of new faults as the 2012 Indian Ocean earthquakes.

Summary

Focal mechanisms of tectonic earthquakes generally follow the deformation style that is expected from the plate tectonic settings they occur in. Thrust mechanisms are observed in subduction zones, collision zones, and other regions of compressional deformation. Normal-faulting earthquakes occur along mid-ocean ridges and in zones of continental extension. Strike-slip earthquakes are observed along transform faults in the ocean and on land where plates or crustal blocks slide laterally past each other. Most earthquakes occur at plate boundaries, but some do occur inside plates (intraplate earthquakes) away from boundaries. Plate boundaries in continental environments are usually broader than their oceanic counterparts. Deep earthquakes are restricted to regions where ocean

lithosphere is recycled back into the mantle at subduction zones. The largest earthquakes are shallow-dipping subduction zone thrust earthquakes.

This entry only provides a general overview of tectonic earthquakes and their source mechanisms. Analysis of seismological data of individual earthquakes and earthquake sequences has in many cases shown complex rupture behavior involving several active faults, which may have different orientations or even a different sense of motion (such as strike-slip and normal faulting or strike-slip and thrust faulting on nearby faults). In addition, slip on faults is not necessarily equally distributed on a fault patch that ruptures during an earthquake; instead slip may show large spatial variations. The reader is referred to the seismological literature for more information on these topics.

Earthquake Mitigation Strategies Through Insurance

Introduction

Insurance can be a powerful *ex ante* strategy in an earthquake risk mitigation framework. Its primordial objective is to provide monetary compensation for damaged assets or lost income but, in addition, it can help achieve other important goals for society such as the establishment of safer building practices, the dissemination of risk information, and the promotion of financial responsibility. Recent scenarios in which insurance has proved most successful suggest strong synergistic effects with other risk mitigation strategies, such as construction regulation and socioeconomic policy.

The study of catastrophe insurance has grown in the last few decades to a burgeoning field bringing together contributions from the private, public, nonprofit, and academic sectors and spanning many varied disciplines. This paper aims at providing a general overview of earthquake (re) insurance strategies without being exhaustive. As earthquake perils are rarely considered in isolation, a review of earthquake insurance necessarily overlaps with broader catastrophe insurance literature.

The usage of earthquake and catastrophe insurance throughout the world is still limited. Guy Carpenter (2014) estimates that 70 % of global economic losses from natural catastrophes were uninsured between 1980 and 2013. Moreover, as the risk exposures grow at a faster pace than insurance, the gap keeps widening.

The insurance and reinsurance industry addresses this challenge via a variety of solutions. Private homeowners may have access to earthquake insurance products that can be purchased individually or through collective, often compulsory, mechanisms such as insurance pools or catastrophe funds. Insurance companies aggregate risks and have access to international reinsurance but also to new instruments in the form of catastrophe bonds or derivatives. These solutions, at the frontier between the traditional insurance market and the financial markets, have also made it possible for sovereign governments to access reinsurance through more varied capital providers.

The first section of this paper establishes the general workings of the modern (re)insurance sector, with a brief look at its history and highlighting the experience in Chile after the 2010 Maule earthquake, as an example of a coordinated financial and political strategy.

The second section focuses on catastrophe risk models, the technology that makes global risk transfer more seamless and which since the 1980s has had an enormous impact on the industry. The discussion addresses earthquake risk models in particular. These models have played an important role in advances in financial tools that have brought an affluence of capital into earthquake reinsurance. Alternative risk transfer, the convergence market, CAT bonds, parametric solutions, industry indices, and modeled loss triggers, and their importance in earthquake risk transactions are addressed in the third section of the paper.

The aggregation of individual risks and their international transfer is typically facilitated by national private insurance markets. In cases where domestic insurers are unable to accomplish these tasks, state or governmental schemes can be an alternative or a complementary approach. Risk pools, catastrophe funds, or sovereign risk transfer are strategies that a country might adopt with the aim of aggregating and sometimes transfer individual risks. These systems are treated in the fourth and fifth sections of this work where the varied experiences of Turkey, New Zealand, Mexico, and the Caribbean are briefly described.

Broader access to insurance, like broader access to safe building practices, health, or other societal infrastructure, remains an important challenge for developing countries. Micro-insurance systems and community-based parametric schemes are the topic of the final section of the paper.

The Insurance and Reinsurance System

Insurance has a long history. Forms of risk sharing have been documented since early human civilization in Mesopotamia, but the origins of what is known today as the modern insurance and

Earthquake Mitigation Strategies Through Insurance, Fig. 1 A simplified schematic view of the (re)insurance market

reinsurance industry can be traced back to the seventeenth and eighteenth centuries (Swiss Re 2013; Wirtz 2013). During that period, large catastrophic events such as the Great Fire of London of 1666 or the Lisbon earthquake of 1755 cemented the importance of insurance principles considered fundamental today, such as the need for global diversification of risk and the necessity of understanding the underlying physical mechanisms. Probability theory, pioneered by Blaise Pascal, Jacob Bernoulli, and Pierre de Fermat, marked the beginning of risk quantification using mathematical approaches and establishing the foundation of modern actuarial practices.

As the concentration of valuable assets has increased in locations susceptible to natural disasters, the risk exposure has also grown. The 1906 San Francisco earthquake and the ensuing widespread fire constituted the largest catastrophe loss the (re)insurance sector had experienced at the time. Since then, catastrophes have grown more and more costly reaching the estimated US\$210 billion loss caused by the 2011 Tohoku earthquake in Japan (Munich 2013). Moreover, a highly connected international economy has uncovered new vulnerabilities derived from supply chains that can be disrupted by disasters once considered distant (Nanto et al. 2011).

Since catastrophe events are, however, relatively rare, there is a pervasive lack of reliable experience data on their likelihood and consequences. Therefore, assessing and pricing catastrophe risk constitute challenges that would persist until the appearance of numerical simulation models during the second half of the twentieth century. Thanks to this innovation, the quantification of probabilities and effects of physically complex catastrophes slowly starts becoming a standard practice.

Today, the (re)insurance industry is a sophisticated amalgam of specialties and entities connected through a variety of global links. To understand how this risk management engine works, it is useful to consider a simplified view of the transactional relationships that exist in the (re)insurance market (Fig. 1).

Insurance is an arrangement by which a party (the insurer) agrees to compensate another party (the insured) for a set of specific future losses in exchange for a periodic payment (premium). Earthquake insurance policies may cover damages to the built environment, injury, casualty, and business interruption. Both private individuals and companies purchase insurance products to protect their assets and in so doing cede their risk to an insurance company, which effectively

acts as a risk aggregator and diversifies the risk across the population.

An insurance company may in turn cede part of its risk to one or several reinsurance companies, who trade globally and therefore diversify risks further. To share some of its acquired risks, a reinsurer may also “retrocede” parts of their portfolios to other reinsurance companies.

Insurance or reinsurance brokers are intermediaries whose objective is to optimize access to affordable coverage. A retail broker assists individual policyholders in obtaining the most appropriate policy to fulfill their needs from the most adequate and affordable insurance provider. Similarly, a reinsurance broker assists insurance companies to access reinsurance worldwide and find the most appropriate coverage at the best prices. They also work with reinsurers who wish to obtain retrocessional coverage. In addition, brokers may provide a series of services such as claims processing, analytics, and strategy consulting among others.

Today’s reinsurance market has a very strong link with the broader financial and capital markets, through what is known as alternative risk transfer or ART. The most common ART technique consists of securitizing the risk in such a way that it can be sold in the form of a bond to financial investors, who in return for providing capital, obtain an interest on their principal. Sovereign governments can also interact with the capital markets to obtain reinsurance funds through catastrophe bonds. This niche “convergence market” brings capital from financial institutions into reinsurance operations. Note that, as shown in Fig. 1, individuals and companies not only participate actively in the subscription of insurance but, through hedge funds that purchase catastrophe bonds, also contribute to the provision of capital for catastrophe reinsurance.

Today, the reinsurance sector includes large, diversified companies that actively trade in a variety of risks worldwide. Table 1 shows the 15 largest reinsurers according to the net reinsurance premium written in 2012 (Standard and Poor’s 2014).

An example of how insurance systems provide earthquake risk mitigation was recently seen in

Earthquake Mitigation Strategies Through Insurance, Table 1 Largest reinsurers by 2012 net reinsurance written premium (US\$ m)

Chile in 2010, as the country faced an economic loss estimated at US\$30 billion arising from the February 27, M_w 8.8 Maule earthquake off the coast of Concepción (Siembieda et al. 2012). Chile enjoys a strong presence of insurance companies that were able to assume close to one third of the total economic loss, about US\$8.4 billion in insured damages (Marsh 2014). These insurance companies were in turn well connected to the global reinsurance markets that provided them coverage to an astounding 95 % (Aon Benfield 2011). This means that most of the insured loss was swiftly transferred to the international reinsurance markets, where it had little impact in the finances of large capital providers. With this robust system in place, Chile’s private market effectively transferred about 30 % of the total economic loss caused by the Maule event outside its borders without any direct government intervention.

This success story worked hand in hand with Chile’s strong enforcement of good construction practices over the decades coupled with compulsory subscription of earthquake insurance for all properties purchased with a mortgage. Without a strong legacy of proactive construction

regulation, insurers would not be easily drawn to this market. And without the compulsory system, the growth of insurance penetration would be severely hampered. Indeed, many owners who had purchased their property outright with cash, a well-established investment strategy in Chile, had no insurance protection at the time of the event.

Regulation and social policies stimulated the growth of the insurance market, and the combination of these “hard” and “soft” resilience strategies was identified as highly effective during the early recovery period (Franco and Siembieda 2010). Much of the success of the insurance system in the Maule event was ultimately attributed to the fast claims settlement process. Ninety percent of the claims were reported by affected households within the first 30 days after the event, and more than 75 % had been settled within less than a year (Marsh 2014).

Quantifying Earthquake Risk and the Rise of CAT Models

The transfer of earthquake risk from Chile to the rest of the world is possible at a global level in great part due to the existence of tools that help to quantify it. These tools are known today as catastrophe or CAT risk models.

The insurance and reinsurance industry has traditionally used historical loss records to price fire, life, theft, and other risks on which there is plenty of experience data, and catastrophes were originally considered in conjunction with more common hazards. Ignoring their specific potential loss contribution resulted in unforeseen insolvencies for the insurance industry in events like hurricane Andrew in 1992. In order to better assess catastrophe risks, companies needed experience data that wasn't available.

During the late 1980s and 1990s, new risk assessment platforms were being developed and deployed in the market. Grossi and Kunreuther (2005) present a comprehensive view of the history and evolution of numerical CAT models that simulate the physical processes involved in catastrophe events.

The paper by Clark (1986) brought the concept of Monte Carlo simulation applied to the assessment of hurricane losses to the actuarial community and paved the way for the foundation of the first catastrophe modeling company, Applied Insurance Research, in 1987. Clark relied on the visionary numerical approaches developed by Friedman (1975) and others. Early earthquake simulation models were simultaneously being developed in California supported by new probabilistic methods (Cornell 1968; Esteva 1970; McGuire 2008).

Earthquake models have become extraordinarily complex, and teams that develop them have grown to include a wide array of specialists such as seismologists, geologists, engineers, statisticians, and financial and software experts. Most commercial earthquake models fundamentally consist of five important modules as shown in Fig. 2. The first generates an event catalog, a set of simulated events compatible with the available knowledge on the seismicity of a specific territory. This knowledge may include fault location data, recurrence intervals, fault geometry, kinematic analyses, etc.

The second module uses ground motion prediction equations, soil data, and fault-related effects, among other parameters, to generate fields of hazard intensities associated with each of the earthquakes contained in the event catalog. These ground motions are in turn fed into a process that calculates possible damage distributions across the affected area for different types of structures. The crux of this vulnerability module consists of a set of mathematical relationships in the form of damage functions or fragility curves derived from structural engineering techniques such as the capacity spectrum method or nonlinear dynamic analysis. Exposure data from the user serves to define the types of properties for which the analysis needs to be executed. Lastly, the financial module applies the terms contained in (re)insurance policies in order to obtain a monetary estimate of insured loss based on the computed physical damage.

Only three model development companies, AIR Worldwide, EQECAT, and Risk Management Solutions (RMS), had a serious foothold in

Earthquake Mitigation Strategies Through Insurance, Fig. 2 Basic anatomy and elements of an earthquake risk model

the industry during the early years of CAT modeling. Later, other groups started operations in the market occasionally specializing in regional or peril-specific models such as Empresa de Riesgos Naturales (ERN) based in Mexico and with a very strong local relevance in Latin America or Risk Frontiers based out of Macquarie University in Australia and specializing in Asia-Pacific perils. Initiatives like the Oasis Loss Modeling Framework aim at lowering the barrier to entry for academics, consultants, and other market participants. The philosophy of this effort is to create a standardized platform that liberates potential entrants from the common pains of software development and from the relatively specialized financial computations involved in reinsurance analysis. In this way, scientists, engineers, and risk experts may be able to deploy their knowledge more seamlessly onto channels easily accessible by the industry.

During this technological revolution that started in the late 1980s, catastrophe risk (re) insurance has changed enormously. Rare would be the case today that an insurance or reinsurance company managed their catastrophe risks without any usage of CAT models. In the absence of actual loss experience data, these numerical tools have been successful at leveraging scientific information to produce a large body of simulations from which the market can now objectively assess and price risks – albeit with significant

limitations and uncertainties. As models become more ubiquitous, the quantification of uncertainty has gained in importance. Several studies have addressed this topic in the context of hurricane (Miller 1999; Major 1999a, b) and earthquake models (Spence et al. 2003). These tools are also still of limited use to address the occurrence of very large or very rare events. When the scientific knowledge is insufficient, all models tend to fail, as was evident in Japan when the M_W 9.0 Great Tohoku earthquake struck in an area where only up to M_W 8.4 events were thought possible.

The numerical estimates from CAT models make it possible to calculate the frequency of loss, which is expressed in the industry as an exceedance probability curve or “EP curve,” a relationship between the value at risk and its probability. This information is critical to price an insurance policy or a reinsurance contract. The pure premium of an insurance policy is defined as its associated average annual loss, and solvency requirements are often expressed as probable maximum losses at specific return periods, typically at 100 years or 250 years.

By using numerical models to estimate the necessary metrics, the industry has managed to overcome the immediate problem of lack of historical experience. However, the battle is not over. Data on physical and economic losses that would help produce better models continues to be scarce, often at disparate resolutions, and

of varied quality. Therefore, the industry continues to look at diverse scientific or professional initiatives such as the Global Earthquake Model or the Learning from Earthquakes initiative spearheaded by the Earthquake Engineering Research Institute (EERI) as extremely valuable contributions.

Alternative Risk Transfer Solutions

CAT models have improved the way in which the market manages and prices its catastrophic risks, and moreover, they have had a great impact on the industry by opening new avenues to transfer risks through the capital markets with more transparency.

The financial markets have increasingly shown interest in catastrophe reinsurance operations as a source of diversification for investment portfolios. Through a series of new instruments, investors have traded in catastrophe risks thus acting as an alternative source of reinsurance capital. These alternative risk transfer (ART) solutions are today a common way to interact with the “convergence market,” the space where finance meets insurance (World Economic Forum 2008).

CAT bonds have probably been the most successful instrument used to “package” catastrophe risks into a securitization. This solution consists of creating a special purpose vehicle, which acts as a reinsurer to a single entity and which holds the bond principal invested in safe, low-risk, short-term securities. Cummins (2008) presents a comprehensive view of the history and types of securitizations and derivatives that have been used in the market.

Capital providers have had an interest in isolating catastrophe risk to avoid other components of risk that are already present in usual financial portfolios. Fully collateralized CAT bonds, for instance, have attracted interest since they eliminate the risk of default of the parties involved.

Similarly, moral hazard present in traditional indemnity-based (re)insurance processes is also undesirable for the capital markets. This problem arises when a party can potentially misrepresent

the actual loss with the aim of obtaining a financial advantage. When the covered party experiences a damaging event that causes loss, it issues a claim to the (re)insurer. This, in turn, assesses the damage through a claim-adjusting process and establishes the corresponding payment, and the (re)insured is compensated accordingly and depending on the policy conditions of the agreement. In addition to being very expensive and cumbersome, claim-adjusting processes provide opportunities for the claimant to exaggerate the loss or for the insurer to downplay it. Capital providers who do not have the mechanisms to assess the quality of the data provided during this process have a vested interest in avoiding it.

With the aim of reducing moral hazard, new techniques for risk transfer became popular during the 1990s (Bisping 2013). Indexed, modeled loss, or parametric solutions remove the need to assess particular losses to a portfolio by tying the payment of recoveries to an independent proxy.

PROPERTY CLAIM SERVICES (PCS), a company operating in the USA, or PERILS, a similar entity operating in Europe, collect loss data from the major insurance companies after a catastrophe and aggregate them into an overall loss estimate. Risk transfer solutions based on these market estimates tie particular recoveries to the overall loss reported by the insurance market. By removing the direct connection between recoveries and particular portfolio losses, moral hazard is greatly diminished. If the event created a large loss for the insurance industry as a whole, it seems intuitive that recoveries for a particular insurer should be somewhat proportional to the overall loss. Naturally, this type of index works best for large companies whose portfolios mimic the distribution of the entire industry. For companies that operate within an industry niche, these types of solutions need to be tailored somehow since they may involve too much “basis risk,” the potential difference between actual losses and recoveries.

Modeled loss solutions base their payments on the loss produced not by the event itself but on the loss estimated by a numerical CAT model. The model is run after an event assuming certain parameters that match measurements from the

event. For instance, an earthquake model that accounts for epicentral location, magnitude, depth, and rupture length of the event may be run setting these parameters equal to estimates provided by the United States Geological Survey (USGS). Further constraining of the model may be accomplished by generating a series of stochastic footprints and identifying those that match more closely the observations obtained from a network of seismometers, if these data are available.

Although modeled loss solutions bypass the claims process, ambiguities may still creep up into the post-event loss calculation (PELC), a series of activities undertaken by a consultant or calculation agent in order to run the model and determine trigger conditions and index values. These steps often involve models that contain significant intellectual property from their developers and whose technical details may not be fully disclosed. Therefore, the intimate workings of modeled loss indices are usually not well understood by parties external to the transaction, and outside investors may feel that they don't have enough information about the likely range of outcomes.

Parametric (re)insurance bases payments neither on the direct observed damages nor on modeled estimates of loss. Rather, these solutions use measurable parameters of the physical event to determine the payouts. Within this class, two types of solutions have been used in the market successfully: *first-generation* CAT-in-a-box triggers and *second-generation* parametric indices.

CAT-in-a-box triggers associate discrete payments to a set of physical event parameters such as magnitude, epicenter location, and focal depth. They are discontinuous in nature and typically involve significant basis risk. Attempts to reduce the basis risk associated with these transactions have consisted of optimizing the trigger thresholds (Franco 2010) or discretizing the parameter domain (Franco 2013).

Transactions that rely on geographically distributed parameters of the event, such as ground motions, have also appeared in the market in the form of *second-generation* parametric indices. These indices are computed as a weighted sum of some mathematical expression, often

polynomials, evaluated at a set of locations using a ground motion metric as the main variable. Typical metrics are peak ground accelerations, spectral acceleration at a particular natural period, or some other descriptors of site-specific shaking like *Shindo* intensity in Japan.

Second-generation parametric indices are generally considered “better” than first-generation solutions because the correlation between losses and local shaking intensity is assumed to be stronger than between losses and the main event parameters of magnitude and epicentral location (Goda 2013). However, in a real scenario, the uncertainties affecting ground motions used in second-generation parametric indices are typically much greater than those affecting the main parameters of the event. Quality comparisons between triggers often remain difficult to pursue since both solutions are dependent on a plethora of design parameters such as resolution used, number of stations, etc.

The continued appearance of both, first- and second-generation solutions, suggests that there is space in the market for a variety of products that may coexist and complement one another. Table 2 collects all the parametric earthquake transactions of first and second generation (trigger type) since 1997 (compiled from www.artemis.bm). Cases in which there is high uncertainty in the exposure distribution could favor first-generation approaches, whereas cases in which reliable networks of seismometers are present and the exposures are well known could tend to support second-generation approaches. Edmonds (2013) provides a market perspective on some of the transactions used in the recent past, and in particular the Muteki Ltd. CAT Bond that was issued in 2008 to protect the large mutual Zenkyoren in Japan, whose trigger mechanism was activated during the M_w 9.0 March 11th 2011 Tohoku event and which provided US\$300 million in recoveries. In some occasions, the lack of a reliable network of seismometers has been circumvented by simulating the response of a set of “virtual” stations (identified as “V” in the trigger type of Table 2) through ground motion models such as the USGS’ ShakeMap or PAGER systems (Wald et al. 2008).

Earthquake Insurance Pools

It is convenient for the effective usage of risk transfer tools that risks are properly aggregated, or “pooled,” in the first place. Individual property risks are grouped into larger portfolios through the standard operations of insurance companies, but penetration of voluntary catastrophe insurance is often low. To boost the take-up rate and aggregation of individual risks, other instruments can be used, most prominently the creation of risk pools.

The main purpose of a pool is to create a compensation fund that works on the principle of solidarity. If an entire community is exposed to a set of perils, all members in the community contribute a premium to the pool, which later can be used to pay for damages incurred. Pools differ by their premium collection mechanism, by the split of financial responsibilities between participating actors, by their relationship with broader reinsurance networks, and by the level of involvement of public versus private entities (Consortio de Compensación de Seguros 2008). On this last item, it should be noted that incentives and subsidies provided through public entities for the management of risks may have strong beneficial effects on society, but they may also lead to difficulties in assessing the actual costs and value associated with such measures.

Switzerland’s insurance sector formed the first formal catastrophe insurance pool in 1939,

known as the Swiss Natural Perils Pool. Although this pool does not yet cover damages from earthquakes across all Swiss cantons, it covers a variety of other perils such as windstorm, hail, avalanche, and snow pressure (Schweizerisches Versicherungsverband or SVV 2014). The Swiss pool is managed by the association of insurers acting in coordination with the national and regional governments.

The Consorcio de Compensación de Seguros, another early example of a pool, was created in 1941 after the Spanish Civil War (1936–1939) to compensate losses derived from rioting during the war years. In 1945, the Consorcio expanded its mission and turned into a more general compensation pool that includes damages from catastrophic perils. It paid, for instance, a total of €489 million to compensate losses from the Lorca M_w 5.1 2011 earthquake in southern Spain (CCS 2014). The Spanish pool is a public entity that operates independently from the insurance industry but that receives the appropriate contribution from policies underwritten in the market. While it does not seek reinsurance in the international market (thus providing no international risk transfer), other pools actively look for this financial support.

New Zealand’s Earthquake Commission (EQC), for instance, expects to obtain about NZ\$4.5 billion in reinsurance recoveries for the Christchurch earthquake sequences that started in February of 2011 (EQC 2013). In June 2013, the

Earthquake Mitigation Strategies Through Insurance, Table 3 Existing national catastrophe pools (World Forum of Catastrophe Programs 2014)

Country or region	Year of inception	Pool name	Summary of characteristics
California (USA)	1996	California Earthquake Authority (CEA)	Provides direct insurance for earthquake residential exposures, participation of insurers and reinsurers is voluntary
France	1982	Catastrophes Naturelles (CatNat)	State-owned system, compulsory participation, premiums collected through commission on standard fire policies
Iceland	1975	Vidlagatríggjng Islands	State-owned system, compulsory participation, premiums collected through commission on standard fire policies
Japan	1966	Japan Earthquake Reinsurance Co. Ltd. (JER)	Privately owned by association of reinsurers, compulsory excess of loss cover, residential exposures, state backed
Mexico	1996–1999	Fondo de Desastres Naturales (FONDEN)	State-owned system, publicly financed, for ex ante and ex post activities
New Zealand	1993	Earthquake Commission (EQC)	State-owned system, compulsory participation, premiums collected through commission on standard fire policies
Norway	1979	Norsk Naturskadepool/ Statens Naturskadefond	State-owned system with participation of all nonlife insurers covering natural disaster damages, premium established by pool, collected by insurers
Romania	2009	Natural Disaster Insurance Pool (PAID)	Jointly owned company by insurers, compulsory dwelling cover for earthquake, flood, and landslide
Spain	1941–1945	Consorcio de Compensación de Seguros (CCS)	State-owned system, compulsory participation, premiums collected through commission on standard fire policies
Switzerland	1939	Swiss Natural Perils Pool	System promoted by the association of Swiss insurers, premiums collected in conjunction with standard policies
Taiwan	2001	Taiwan Residential Earthquake Insurance Fund (TREIF)	State-owned system, compulsory participation, premiums collected through commission on standard fire policies
Turkey	2000	Turkish Catastrophe Insurance Pool (TCIP)	State-owned system, compulsory participation, TCIP policies distributed by accredited insurers

EQC had disbursed a total of NZ\$5.7 billion in claims payments and had collected a total of NZ\$1.8 billion in reinsurance. The pool still contained NZ\$2.9 billion then although the expectation was that it would be completely depleted by the time all claims have been settled. The fund would have been further impaired to respond to the Christchurch events without the support of reinsurance.

In Asia, two prominent programs in Japan and in Taiwan address the pooling of risks through two distinct strategies, the first through the participation of private companies in a state-backed reinsurance provider and the second using a

similar mechanism to EQC in New Zealand, through a compulsory fee on standard fire policies. Many of the national pools currently in operation (summarized in Table 3) show distinct degrees of involvement of different governments (Nguyen 2013). The design criteria of each pool depend on history, on the existing insurance mechanisms, on government capacity, and on the objectives of each particular effort.

While the main purpose of the pool mechanism is to provide monetary compensation, it can have a strong socioeconomic effect as well. The Turkish Catastrophe Insurance Pool (TCIP), established in 2000 after the Kocaeli and Düzce

earthquakes of 1999, has been a conduit to accomplish many objectives such as international risk transfer, reduction of liability of the government, prevention of further taxation, promotion of good construction practices, and an increase of social cohesion. Similarly to the EQC, the pool has also financed education and research projects in order to foster the understanding and communication of risks.

TCIP has typically accessed the traditional international markets for reinsurance. In 2013, it decided to complement this coverage through an ART tool called Bosphorus 1 Re Ltd. This parametric earthquake transaction is based on a ground motion index that relies on a network of seismometers around Istanbul managed by the Kandilli Observatory and Earthquake Research Institute. The CAT bond was oversubscribed when it hit the market, showing the great interest of global financial entities to participate in the reinsurance of TCIP as a diversifying risk (Artemis 2013). It also provided TCIP with coverage at advantageous prices.

The example of Turkey's securitization appeal is often compared to the success of a series of CAT bonds issued by FONDEN in Mexico. The FONDEN system is fully backed by the Mexican government, without any direct participation of the insurance industry. Originally established as an agency to provide funds after catastrophic events, it has grown to incorporate risk financing among its responsibilities. Mexico has been tremendously innovative in governmental risk transfer and is an often-cited success story of sovereign risk transfer, an alternative solution to traditional reinsurance for governments.

Sovereign Earthquake Risk Transfer

The cases of Chile, New Zealand, or Turkey illustrate how countries can effectively transfer catastrophe risk to the global markets via their domestic insurance systems. A country may seek financial protection from the global markets in a more direct fashion in what is referred to as "sovereign" risk transfer. The development of insurance solutions in the sovereign space has

been strongly guided by the Hyogo Framework for Action 2005–2015, which identified the need to promote the development of financial risk-sharing mechanisms, particularly insurance and reinsurance against disasters (Cummins and Mahul 2009). The impact that the Global Facility for Disaster Reduction and Recovery (GFDRR) and the World Bank have had on advances in this field is patent in the solutions implemented during the last decade.

In 2006, the Government of Mexico (through FONDEN) sponsored CAT-Mex Ltd., a parametric catastrophe bond designed to finance rescue and rebuilding costs after an earthquake. The bond successfully transferred US\$160 million of Mexico's earthquake risk to the global financial markets on a parametric basis over a period of 3 years. Several geographic zones were defined and associated with threshold conditions on the magnitude and location of the earthquake that need to be met in order for the coverage to be triggered.

The transaction was deemed successful and the experience was repeated after the bond matured in 2009. Mexico then issued the MultiCat Mexico 2009 bond expanding its coverage to hurricane risk for a total of US\$290 million until 2012, at which point the transaction was reissued for US\$315 million under the name MultiCat Mexico Ltd. (Series 2012-1) maturing in 2015.

The 2009 bond was oversubscribed, with demand for the Mexican bonds outpacing supply. The bond originally required \$250 million of coverage but was upsized to \$290 million to satisfy market demand, which in turn translated into more attractive pricing for Mexico.

Over the last decade, Mexico has established itself as the first sovereign country that has effectively transferred some of its catastrophe risk outside of its borders via these novel instruments. The Mexican experience has been pioneering and has attracted much attention and interest. It has also been the subject of several studies that aimed to describe the features of the first transaction (Cardenas et al. 2007), optimize the efficiency of these tools in the context of other reinsurance strategies (Härdle and López Cabrera 2010), or

give a more comprehensive perspective on the construction, implementation, and lessons learned from these solutions (Michel-Kerjan et al. 2011). In addition, trade journals such as the Bermuda-based specialist website www.Artemis.bm have followed the activity related to the Mexican bond issuances and have made available plenty of interesting information as to how markets have reacted to these transactions over the years.

The financial markets, by welcoming Mexican catastrophe risk, have proved that the issuance of these bonds is a plausible strategy for a country to transfer its risks. However, the case of Mexico involves one single country with a strong legal and financial system in place and with a long history of insurance experience. Other emerging countries with fewer systems in place require other strategies to successfully leverage risk transfer solutions.

This was the motivation for the creation of the Caribbean Catastrophe Risk Insurance Facility (CCRIF) in 2007. This institution was formed by 16 Caribbean countries, under guidance from the World Bank, to pool and transfer regional hurricane and earthquake risks to the global financial markets (World Bank 2008). The trigger mechanisms were also parametric, conceptually similar to those used in Mexico. However, the compensations were, in general, not designed to finance long-term operations but to provide a cash injection to address what the CCRIF defined as the “liquidity gap,” the period of time directly after the emergency response and before other assistance funds can be accessed for long-term recovery. Countries like Haiti with nonexistent or feeble financial systems in place would have found it hard to access insurance on a stand-alone basis like Mexico did. However, CCRIF has been able to access the reinsurance community and has effectively responded to several events during its existence, benefitting the governments of Anguilla, St. Vincent and the Grenadines, Barbados, Dominica, St. Lucia, Turks and Caicos Islands, and Haiti.

The case of Haiti also brought to light that in order for insurance mechanisms to be effective, some basic governance and finance infrastructure

needs to be in place. After the M_w 7.0 earthquake of January 2010, the country was devastated (DesRoches et al. 2011). The government fell in complete disarray, and chaos ensued. When CCRIF communicated that it was ready to make a payment of about US\$7.7 million (about 20 times the yearly premium paid by Haiti) as per the pool arrangement, it took some time, in the absence of an operational government and banking community, to find mechanisms to deploy the funds.

Insurance-pooling schemes have provided developing nations with a foothold in the global reinsurance networks. As CCRIF has established itself as a successful operation, similar initiatives have been set in motion in Africa (African Risk Capacity 2012) and in the South Pacific (Pacific Disaster Risk Financing and Insurance Program 2011). Recently, cyclone Ian triggered the payment of US\$1.27 million to the government of Tonga, which participates in this newly created system.

Remarks on Micro-Insurance

Low-income populations in developing nations frequently use community-based financing or insurance schemes, often with great creativity (Rutherford 1999). However, due to the covariant nature of catastrophes, community-based financing techniques are not well suited to respond to events that may affect the entire participating community at once. This has spawned an exploration into whether formal insurance tools can overcome this challenge for developing nations (Linnerooth-Bayer and Mechler 2009).

In general, the few experiences that exist and the analyses carried out suggest that insurance can indeed be a good complement to other risk mitigation initiatives. However, when analyzing the benefits of insurance in a developmental setting, it should not always be considered evident that cash by itself is helpful for long-term recovery or for building future resilience. Monetary support often needs to be accompanied by other initiatives in order to have a truly positive impact on society.

In a recent reconstruction survey in Sri Lanka, eight and a half years after the island nation was hit by the devastating Indian Ocean tsunami of December 2004, Franco et al. (2013) visited several communities along the coast. Differences in recovery outcomes were observed between sites that had been managed by third-party donors versus settlements where owners had been empowered to rebuild through a gradual injection of cash. Through this process, owners were provided a set of cash packages that allowed them to rebuild on their original plot in subsequent phases, assuming that the land remained fit for settlement. At each phase, an inspector would survey the construction quality and would give approval for the next stage, at which point the owner would obtain a transfer of cash through prearranged “tsunami bank accounts.” The outcomes of settlements built by donors on land provided by the government varied in quality, but the feedback on the owner-driven construction scheme was almost universally positive, which suggests that in the presence of other supporting mechanisms, access to cash can truly play a powerful role in a successful recovery.

Micro-insurance initiatives have started addressing part of this problem by tying insurance products to other broader services that integrate the population in formal financial networks. Mechler et al. (2006) discuss several property insurance “bundles” connected to other social and financial services in Nepal, Bangladesh, India, Pakistan, and Malawi. Insurance can have greater societal impact if its purchase links communities with educational initiatives, construction oversight, or risk mitigation, as echoed in the objectives of Turkey’s TCIP program.

Since micro-insurance solutions made their appearance in the early 2000s, the experience so far is very limited. In the meantime, significant challenges have been identified in the marketing and deployment of insurance solutions within populations that are remote or where great educational and cultural barriers exist. This has been partly addressed by the usage of parametric solutions, which as described above, suffer from basis risk but also help bypass claim processes that

would be especially costly in locations with difficult access and lack of skilled adjusters.

In this context, India has made important advances by implementing indexed schemes for crop insurance, successful in great part thanks to the governmental policy that requires the insurance sector to service the low-income populations (Mechler et al. 2006; Giné et al. 2010). Other countries in Africa, Asia, and Latin America are making use of similar schemes (Ibarra 2009).

Earthquake-specific insurance programs have been studied for implementation in China, where these types of solutions have the potential to fit well. China has a sophisticated insurance market, well connected to the reinsurance industry (Wang et al. 2009) but with many needs in low-income communities in earthquake-prone areas. In particular, parametric solutions have been studied for deployment using modern CAT modeling techniques (Del Re et al. 2008).

Summary

Insurance successes, large or small, have been witnessed in events like the Maule earthquake in Chile or the Christchurch earthquakes in New Zealand. Many experiences remain highly imperfect, but in the meantime, countries like Turkey and Mexico have made great strides in advancing their earthquake risk management strategy. Embracing ex ante risk management tools, many countries are slowly assuming more and more responsibility over their future.

Earthquake (re)insurance systems offer exciting opportunities for development along all the dimensions presented in this paper. At the core of national economies, insurance industries need to be established and strengthened in order to formally manage existing risks. In countries that lack a strong socioeconomic foundation, multi-national risk pools or sovereign risk transfer remain open options to slowly reshape or complement ex post response strategies with proactive risk management. Technological advances made in the last few decades have helped communities assess their exposures to a much larger

degree than they were once able to, but refinements of these computational tools are continuously being made to improve the quantification risk. In parallel, new promising paths in alternative risk transfer continue to be charted in the financial markets, and new products and distribution channels continue to be explored at the community level through micro-insurance initiatives.

Experiences suggest that availability of capital after catastrophe events at an individual and governmental level can support a better and faster recovery and can ultimately increase a society's resilience. Systems that facilitate the rapid deployment of funds can provide almost instant liquidity at a time of need. Earthquake insurance can therefore be a strong component of any seismic risk mitigation framework with potentially synergistic effects with other coexisting measures such as risk education, construction regulation, and socioeconomic policies.

The (re)insurance sector and society as a whole are still learning important lessons from earthquake events today, and much work remains to be done. Earthquake and tsunami perils are often perceived as "distant" in time and space, and this often hinders the implementation of risk management policies and measures. However, the combination of documented growing economic losses, small overall global earthquake insurance penetration rates, and a large supply of capital means that an increasing portion of the financial burdens imposed by earthquakes worldwide could be assumed by global financial networks rather than by often fragile local economies. This represents a challenging task but also an exciting prospect.

Earthquake Protection of Essential Facilities

William T. Holmes¹ and Robert K. Reitherman²

¹Rutherford + Chekene Engineers,
San Francisco, CA, USA

²Consortium of Universities for Research in
Earthquake Engineering, Richmond, CA, USA

Introduction

Essential facilities, such as hospitals, emergency communications centers, and fire stations, are intended to provide an essential service immediately following an earthquake, and thus, a key criterion in their design that distinguishes these facilities from ordinary occupancy construction is the protection of their functionality. The hospital should continue to provide medical care; the dispatching of emergency vehicles should continue without an interruption caused by damage to a communications facility; and fire stations should be able to respond to the need for fire fighting, search and rescue, and hazardous materials releases. There are also nongovernmental facilities whose services or products are so valuable to a company that functionality is protected with on-site structural and nonstructural measures discussed here. Multifacility organization-wide or corporate-wide planning has also been employed so that redundant facilities are sited so that they are not all in the same seismic region.

Building codes as well as the design standards for many components of utility and transportation systems typically set safety as a minimum objective. In some cases, for example, an art museum or historic building, protection of the property itself is another criterion that is also included. As a practical matter, achieving the objective of post-earthquake functionality typically requires meeting and exceeding those two other kinds of objectives, safety and property protection, making it difficult to achieve. If controlling damage to a very low level and also providing backup

Earthquake Protection of Essential Facilities, Fig. 1 One of two completely collapsed buildings at the Veterans Administration Hospital, 1971 San Fernando

earthquake (Source: US Army Corps of Engineers, NISEE-PEER library, University of California, Berkeley)

on-site utility services were easy to achieve without a significant cost premium, most facilities would already be designed for this performance level, whereas in fact, comprehensive protection of functionality of a facility is relatively rare.

Historic Examples

There have been many examples of earthquake disruption of essential facility operations, dating back decades and continuing to the present. One of the earliest particularly instructive earthquakes was the 1971 San Fernando earthquake in the Los Angeles area. Seven major medical facilities were badly damaged: Foothill Medical Center, Pacoima Lutheran Medical Center, Pacoima Memorial Lutheran Hospital, Holy Cross Hospital, Indian Hills Medical Center, the Sylmar Veterans Administration (VA) Medical Center, and Olive View Medical Center (Jennings 1971; Lew et al. 1971; Johnston and Strand 1973). As a result, 1,553 hospital beds were out of service (Oakeshott 1975), and instead of being able to provide the post-earthquake supply of medical care for injuries in the area, damaged hospitals

became additional demand on the medical and rescue resources of other facilities. The Veterans Administration complex of buildings in Sylmar was the scene of two complete structural collapses. See Fig. 1. At the Olive View Medical Center nearby, the 750-bed main hospital building suffered such severe soft story damage that it was evacuated and torn down, only 2 months after it had been built (Fig. 2). In addition, the two-story Olive View Psychiatric Building at that complex experienced a complete ground-story collapse (Fig. 3); several unreinforced masonry buildings on the grounds collapsed; damage to the fire station located on the grounds required lengthy extrication of the equipment; reinforced concrete canopies collapsed onto ambulances (Fig. 4); damage to the backup power system (Fig. 5) and to the entire array of nonstructural components – elevators, windows, partitions, ceilings, piping, and medical gasses – occurred (Ayres and Sun 1973); and the equipment and piping in the on-site power plant building was so damaged that its functions were not available (Fig. 6).

Following the San Fernando earthquake, the Veterans Administration adopted seismic

Earthquake Protection of Essential Facilities, Fig. 2 Destruction of a non-ductile reinforced column, main building, Olive View Medical Center, 1971 San Fernando Earthquake (Source: Karl V. Steinbrugge Collection, NISEE-PEER library, University of California, Berkeley)

standards for new facilities that have set the basic standard for protecting essential facilities, including these provisions: structures with more strength and stiffness than normal buildings to minimize damage, protection of nonstructural components to minimize internal disruption, and particular attention to protection of critically important equipment and utilities, including on-site backup capability such as emergency generators and water storage. The Veterans Administration, having a system of healthcare facilities across the United States, also started a program of evaluation of existing facilities and developed new design criteria for new ones (Veterans Administration 1972; Bolt et al. 1975). The state of California enacted the Hospital Seismic Safety Act in 1972 that covered non-federal-government hospitals with similar

requirements (Holmes 2002), and that act clearly stated the goal of keeping hospitals functioning after earthquakes:

It is the intent of the Legislature that hospitals, which house patients who have less than the capacity of normal healthy persons to protect themselves, and which must be reasonably capable of providing services to the public after a disaster, shall be designed and constructed to resist, insofar as practical forces generated by earthquakes, gravity, and wind.

In both approaches, merely setting code criteria was only the beginning, because implementation of the criteria requires a detailed level of quality assurance well beyond that employed for the design and construction of an ordinary occupancy facility. Because at a given point in history the majority of essential buildings that are in existence will almost always greatly outnumber the number of new buildings that will be built in the next few years, to improve the earthquake protection of a region's inventory of essential facilities requires dealing the difficult problems of retrofits to existing construction. In 1994, following the 1994 Northridge earthquake, California took that step in passing SB (Senate Bill) 1953. Although this has resulted in many hundreds of millions of dollars of cost among California's hospitals to upgrade existing hospitals or replace them with new ones, in the process, not only their safety but their ability to function after earthquakes has been greatly improved.

In another earthquake of the early 1970s, the 1972 Nicaragua earthquake that caused great damage in the capital city of Managua, the scope of damage and disruption to essential facilities was extensive (see Fig. 7):

The damage in Managua provides many examples of the need to construct buildings housing essential facilities in a manner such that they will be functional when desperately needed following an earthquake. Most critical facilities in Managua were destroyed. Examples are [figure citations deleted here]: the fire station which collapsed upon the fire equipment, the Red Cross building, which collapsed upon their ambulances and emergency supplies, the INSS Hospital, which suffered severe structural and nonstructural damages making it not just useless, but definitely hazardous to its occupants. The General Hospital also suffered very severe damage. ... (Wright and Kramer 1973, p. 19)

earthquake (Source: Karl V. Steinbrugge Collection, NISEE-PEER library, University of California, Berkeley)

Earthquake Protection of Essential Facilities, Fig. 4 Destruction of ambulances by collapsed concrete canopy, Olive View Medical Center, 1971 San Fernando earthquake (Source: Karl V. Steinbrugge Collection, NISEE-PEER library, University of California, Berkeley)

Many more examples could be cited – see FEMA (2007) – but in this brief review, these two earthquakes are adequate to illustrate the range of disruptive effects, and the 1971 and

1972 earthquakes also approximately date the beginning of the era when focused attention has been given to protecting essential facility functions. Also during this post-1971 or

V. Steinbrugge Collection, NISEE-PEER library, University of California, Berkeley)

post-1972 era, an awareness of the need for functional protection of other kinds of essential facilities evolved. In California, the Essential Services Buildings Seismic Safety Act was passed in 1986.

Structural Protection

Better performance of the structure of an essential building has often been sought in the provisions of seismic codes by increasing the

Earthquake Protection of Essential Facilities,

Nicaragua earthquake
(Source: Karl V. Steinbrugge Collection, NISEE-PEER library, University of California, Berkeley)

design forces. The Uniform Building Code, which was the common code of the Western United States until the inauguration of the International Building Code in 2000, an I or Importance Factor of 1.5 was introduced in the 1976 edition having the effect of increasing the design forces by 50 %. Because inelastic levels of response are still anticipated even for these stronger buildings if severe ground shaking occurs, only increasing the elastic-based design forces is currently thought to be helpful but not sufficient in attaining the performance level of remaining operational. Nuclear power plants are typically designed with the objective of providing so much strength that their structural, as well as key nonstructural, components remain elastic, but that specialized topic is covered in another article and that level of protection is generally infeasible – too expensive and too restricting on the configuration of ordinary buildings. Some inelastic behavior in the structure does not necessarily mean that the operation of the facility has been greatly curtailed, if the design has confined the inelasticity, i.e., damage, to portions of the structure that can absorb that earthquake punishment while still allowing the structure to remain occupiable and operational. A key criterion, and a difficult one to meet, is preventing interstory

drift from reaching levels that result in permanent distortion of the overall structure, a damage state that triggers evacuation.

Although it carries a cost premium, seismic isolation has been increasingly employed since it was introduced in modern form in the 1980s, the first isolated building in the world being the William Clayton Building in Wellington, New Zealand, completed in 1982. Typically, reducing the response of the building to a third of what it would otherwise be, isolation can provide high levels of functional protection, assuming the structure and nonstructural systems are still designed to appropriate levels for that degree of motion. As noted below, because nonstructural components are typically more fragile than the structure, a level of earthquake motion in a building “only” one-third as great as that of the ground’s unreduced level of motion can still be damaging unless appropriate design measures are implemented.

Nonstructural Protection

While it is necessary for the structure of the essential facility to remain safe and serviceable if the facility’s functionality is to be maintained,

it is not sufficient. There are many nonstructural items that must be protected from damage as well, such as emergency power generators, ceilings, fire sprinkler pipes, and elevators, to name but a few. The bare structure of a building, or the supporting framework or tower of a utility component, by itself provides no essential service. The degree of difficulty in protecting essential functions thus is greatly increased beyond the already formidable performance level of confining any structural damage to a negligible level, especially because most nonstructural components are more damageable, that is, they have higher fragilities than the structure itself. Unsecured reagents can fall off the shelves in a laboratory, which can cause a hazardous material release or fire, or both, at very low levels of shaking, to cite one example.

The first comprehensive study of the effects of an earthquake on nonstructural components was for the 1964 Alaska earthquake (Ayres et al. 1973), and that study can still be consulted for a valid overview of the range of damage. Because of the difficulty of providing comprehensive nonstructural protection, unfortunately, many subsequent earthquakes have provided the same basic sorts of examples of damage. Protecting nonstructural components, a topic discussed in a separate article, requires a major effort to go beyond the objective of safety for the occupants and prevention of serious damage to the structure. In a sense, structural engineers deal with one coherent entity in the design of the structure, an integrated structure shown entirely on the structural design drawings and documents, whereas the nonstructural items number in the hundreds or thousands and they are not all under the purview of one design professional. The architect, electrical and mechanical engineers, and specialty designers, such as for fire protection systems or elevators, each separately design nonstructural components. The design professional with the most expertise with regard to bracing and anchorage of nonstructural components, the structural engineer, is only employed when regulations or special attentiveness on the part of the client set that requirement. (Bracing, for example, refers to diagonal struts bracing

a rack containing equipment; anchoring refers to anchor bolts connecting the rack to the floor and or wall.) Adding to the problem is the fact that many kinds of equipment are introduced by the occupant after the building is built and outside the purview of the building code or a design professional, such as the furnishings, file cabinets, and computer equipment in an office setting or the chemicals and related apparatus in a laboratory. Making the problem even more difficult is the fact that even if the design professionals collectively cover all of the necessary nonstructural protective measures, there are then multiple specialty construction trades involved who build those features into the facility. This entry cannot delve deeply into the topic of nonstructural protection, other than to cite in passing a basic evaluation and design manual on the subject, *Reducing the Risks of Nonstructural Earthquake Damage* (FEMA 2011), and a study of the difficulties encountered in developing a coordinated approach to implementing nonstructural protection (Masek and Ridge 2009). The importance as well as the difficulty of ensuring adequate nonstructural performance in an essential facility can be briefly illustrated here using the example of the backup power system.

Picturing a modern telecommunications or medical facility, we immediately note that if the electrical power from the local utility is disrupted by the earthquake – a very plausible earthquake planning assumption – the facility cannot function, unless its own backup power system operates reliably. There are at least six components to an emergency electrical power system; the disabling of any one of which will cause the entire backup power system to fail. Batteries are needed to start the motor-generator set, and these heavy batteries, which thus experience large inertial forces in the earthquake, are only strongly braced if earthquakes are specifically taken into account. The massive motor-generator set itself, often weighing as much as a truck in the case of systems that must supply large amounts of power such as for a hospital, is typically mounted on vibration isolation springs. The springs are designed to filter out the very high frequency vibration of the motor, which would otherwise

propagate through the building and bother occupants, but when the floor is subjected to the lower frequency motions with large displacements of the earthquake, spring-mounted equipment can violently lunge off its supports. Seismically designed products that solve both the motor vibration and seismic response problem are the typical solution today, and existing mounts have been retrofitted with restrainers (“snubbers”). If the batteries remain stable and the motor generator is adequately restrained, the system still needs to have a functional exhaust flue – breakage of which has resulted in filling the generator room with fumes that choke off the engine. In some cases, a generator has been reliably run in tests or for brief power outages, but when run continuously for a day or more, it overheats. The heat from the motor must be dissipated, in the case of large units with water-fed radiator systems. The electrical panel that distributes the power through the facility is another critical component, and on-site fuel, such as oil for a diesel generator, sufficient for several days or longer is necessary as well. In places and eras where providing protection of essential functions is a new approach that is being phased in, singling out the emergency power system has been a strategic place to start (Applied Technology Council 1990). Another way to look at the seismic protection of backup power systems is as a means to evaluate the effectiveness of seismic protection programs. If discussions and planning meetings have gone on for more than a year about how to deal with all the various potential kinds of damage and outages in an essential facility, but if nothing has been done to evaluate and if needed retrofit its backup power system, the program’s effectiveness could be questioned.

Mentioned again here, although it is the topic of a separate article, is the nuclear power plant. The typical seismic design basis is aimed at keeping both structural and nonstructural components elastic, a design approach prohibitively expensive for most essential facilities. Expensive shake table testing has qualified or certified key types of equipment for that industry, and although testing standards vary, some of the sophisticated types of analysis, testing, and

design in that industry have been gradually adapted for use with less critical facilities. In some cases today, key kinds of equipment have been subjected to shake table qualification testing, an approach only relatively recently introduced into some codes and standards, such as the 2005 edition of ASCE 7, the standard referred to by building codes in the United States for determining design loads.

Backups for Essential Systems

Essential buildings are normally dependent on one or more essential systems to provide adequate functionality after an earthquake. Almost all such buildings require electrical power to be delivered to its communications, computer, and other equipment. Hospitals are a special case and in addition require water, medical gasses, and in some cases, waste disposal to continue care for their patients and incoming injured.

Community or regional power systems are susceptible to damage and interruption from earthquake shaking. On-site backup power generation systems, including the generator, starting batteries, fuel and day tanks, cooling systems, and exhaust systems, are typically provided at facilities such as hospitals and fire stations for this reason. However, beyond the anchorage and bracing of this equipment for seismic purposes, discussed above, the amount of on-site fuel must be considered. The California Hospital Program requires enough fuel to run essential systems for 36 hours. The Pan American Health Organization (PAHO), considering hospitals in less-developed countries, recommends fuel for five full days. Almost all hospitals have emergency generators to cover their essential systems for normal system interruptions, which are frequent in some regions, but these outages are typically only hours long, and sufficient fuel for multiple days is often not provided or locally available. In addition, when generators are installed to run for hours, they will often overheat if run continuously for a full day or more. The adequacy of the cooling system therefore must also be considered for generators for essential buildings.

Uninterrupted Power Supply (UPS) systems are often required for computer and/or communications systems and for certain medical equipment in hospitals. These systems are heavy and must be carefully braced and anchored to maintain function during and after earthquake shaking.

Water is another utility that is often necessary for the continued function of an essential facility and also one that is susceptible to interruption of the off-site supply. Besides drinking water, water may also be required at the site of essential facilities for cooling or operation of equipment and for fire sprinklers. For hospitals, PAHO recommends that a hospital site have an emergency supply of 300 l per bed per day, for 3 days. Pumps and on-site filtration, if required, may also require power and supplies that must be provided in the post-earthquake setting.

Most essential facilities are dependent on effective communication after an earthquake. Hard line and cell telephone may not be functional, and backup systems should be provided. Equipment racks used for communication equipment must be able to withstand the shaking. Radio frequencies should be checked for compatibility with outside entities that must be contacted. Shortwave radio and satellite telephones are possible backup systems. Large or multi-site facilities may also need to maintain internal communication, and the viability of the existing systems should be considered.

Access to off-site equipment and supplies may also be cut off after an earthquake. Vehicles that may be needed in the post-earthquake environment must be protected and available. Adequate quantities of supplies needed for post-earthquake function should be stored on-site or reliably available. For example, supplies of medical gasses (oxygen, nitrogen, compressed air) are needed for many functions in a hospital, and medical stores for 3–5 days should be available. Multi-facility systems, for example, a collection of hospitals run by the same organization or agency or several electronics plants or data processing centers of a company, can include in their planning how the services of one or more facilities isolated by a transportation or other off-site outage, or

disabled by on-site damage, can be temporarily supplied by redundant facilities located elsewhere.

Emergency Response

The severity of ground motion from an earthquake is typically unevenly distributed over a region, based on distance from the rupturing fault, direction and sense of fault rupture, local soils and deeper geology, and topography. Vulnerabilities of facilities are also highly variable, if only because the facilities in a region were built at different times to varying seismic criteria. This leads to the likelihood that some essential facilities will be significantly damaged and nonfunctional, while others will remain intact. Mutual aid planning and emergency response agreements are an effective technique for coping with the outages that do occur and capitalizing on those facilities that remain online.

In parallel with the engineering approach of preventing damage is the emergency response approach of quickly controlling damage and providing alternate means of providing service. The key difference between an exercise of a hospital disaster plan for an earthquake scenario as compared to one based on a presumed plane crash or other incident is that the hospital that is expected to suddenly provide an enhanced level of emergency service to the community will simultaneously find itself in a disruptive situation. The hospital that cannot protect itself from disruptive damage in the earthquake is of little use and perhaps a source of demand for emergency services rather than a supplier. Thus, to be realistic, seismic emergency response procedures cannot merely be copied from procedures for other kinds of disasters that do not simultaneously affect the region and the individual facility.

Three examples of communication outages and their effect on emergency response are cited to illustrate the issues involved. In the 1971 San Fernando earthquake, it took 1 h and 22 min before the key response agency, the fire department, knew that two buildings had collapsed at the Veterans Administration Hospital, a hospital

that was part of the urbanized Los Angeles area and was not in an isolated area (Reitherman 1986). Telephone service was out, radio communication was not functional, and although the in-person messenger sent to the nearest fire station to report the need for rescue operations at the hospital delivered that message, it was then confused with the problems at the nearby Olive View Hospital. In retrospect, the single biggest emergency response need in that earthquake was at the VA hospital, where 49 of the 58 fatalities in the earthquake occurred and a massive rescue operation was needed.

Eighteen years later, in the 1989 Loma Prieta earthquake in northern California, the most badly damaged hospital was Watsonville Community Hospital, which had to evacuate its buildings and provide services for in-patients and arriving emergency patients in the parking lot. Outside aide was not requested for several hours, because initial news reports that the hospital heard made it seem that the San Francisco metropolitan area 100 km away was totally devastated and hence aid resources would be focused there. In fact, there were many outside resources that eventually made their way to the hospital when its needs were accurately known.

In the 1994 Northridge earthquake in the Los Angeles area, water lines at the Sepulveda Veterans Administration Medical Center ruptured, which with efficient emergency response should result in prompt water shutoffs of affected zones to minimize water damage and disruption. Instead, patients and personnel, including facilities engineers, were evacuated and did not reenter the building until structural engineers arrived several hours later and declared the building safe for emergency operations such as turning off the water. Effective emergency response planning should include checklists for rapid utilities actions, such as water and gas shutoffs if certain observable criteria are met, and also for rapid safety inspections by engineers under prearranged plans.

New facilities intended for critical post-earthquake functions can be designed in accordance with recommendations discussed here and international standards, but older existing facilities are much more difficult to prepare for adequate

post-earthquake service. Structural retrofit is often expensive, and replacement may take years to plan and build. But honest evaluation of expected structural and nonstructural performance will lead to necessary and often affordable improvements, and more importantly, development of plans to offset functional difficulties.

Summary

Earthquakes have caused disruption of the services provided by essential facilities such as hospitals, emergency communications centers, and fire stations. For the functions of these facilities to be available in the post-earthquake setting, the structure must perform safely and key nonstructural components must be protected. In addition to these engineering approaches, emergency response planning is necessary to identify off-site lifeline systems that could be disrupted by the earthquake, because a facility may need backup systems and supplies to contend with outages to the region's water, power, and transportation systems.

shaking at a specified site will exceed some intensity-measure level of engineering interest in a given time period t . The results of a PSHA have a broad spectrum of end users, ranging from decision-makers who have to provide new codes for designing safe buildings to engineers who must predict potential damage to critical structures. Among all the variables involved in the PSHA computation, this section will focus on the description of the probability models used to build earthquake rupture forecast (ERF) from earthquake rate model in the area under study. ERF allows a modeling of the probability of occurrence of all possible damaging earthquakes in a given region during a specified time span and represents the basis for PSHA. In practice, an incorrect or incomplete representation of the seismicity in space, time, and size may bias the analysis leading to underestimation or overconservatism in the final hazard assessment and consequential direct and nontrivial implications for the compilation of regulations for seismic design.

The Physics of the Problem: From Deterministic Toward Probabilistic Perspective

The elastic rebound theory proposed by Reid (1910) after the 1906 San Francisco earthquake suggests that large tectonic earthquakes occur when the stress exceeds a critical value of the rock strength, producing fractures and relieving crustal strain. In a given area, stress builds up due to tectonic processes ultimately connected to the plate movements. Thus, assuming a constant rate in the stress buildup, the critical value and the consequent earthquake nucleation will be reached at more or less regular intervals. This periodic buildup and release of stress on a given fault represents what is known as *seismic cycle* whose duration is given by the ratio of event-strain release to tectonic strain rate. More precisely, a seismic cycle controls the long-term timing of large earthquakes and comprises three different stages, namely, (i) the interseismic stage during which there is an accumulation of strain

Earthquake Recurrence

Introduction

Probabilistic seismic hazard analysis (PSHA) aims at estimating the probability that ground

energy; (ii) coseismic stage, which corresponds to the stage of principal rupture; and (iii) post-seismic stage during which a new equilibrium is reached. However, comparison of seismic slip distribution with potential slip inferred from geodetic motion measurements demonstrates that not all the stored energy is released through seismic slip but there is a deficit which is attributed to fault creep and aseismic deformation (Bakun et al. 1986).

In this respect, earthquake recurrence refers to the time between subsequent events rupturing on a given segment fault, hence to the period of the loading cycle. Thus, in theory one would think that it is possible to predict the occurrence of future events if one knows the previous history. Indeed, the scheme described so far provides a deterministic representation of the occurrence of a single earthquake on a given structure and may be too simple to depict the real nature of the earthquake recurrence. In this respect, Nishenko and Buland (1987) described three possible factors for the observed variation in the recurrence period. A first factor is a possible change in source size from event to event which would require a different time for restoring the initial stress value, a second factor is a nonlinear strain accumulation in which the strain field initially recovers rapidly soon after the event and then progressively lowers down until the next event, and a third factor is given by the faults' interaction in which strain energy released on one fault segment affects the strain on nearby faults. In addition, the uncertainties of estimations of the earthquake parameters, and the relatively shortness of the seismic records available, make the definition of the seismic cycle even more complicated, leading to a chaotic behavior of the sequences. In this perspective, models of earthquake occurrence are developed in the framework of the probability theory, on which also the PSHA is established.

From a practical point of view, when performing a PSHA, once the seismic zones which represent the potential threat for the site of interest have been identified and modeled (as points, lines, areas, volumes, or single faults) based on the available data, the recurrence of the

earthquakes, in particular of their magnitude should be defined. Two recurrence relationships are generally used: the Gutenberg-Richter (GR) relationship (Gutenberg and Richter 1944) and the characteristic earthquake model (Schwartz and Coppersmith 1984). The GR model assumes that in a given seismic zone, events of all magnitudes (from a minimum to a maximum magnitude value) may occur and are expressed through the relationship:

$$\log N(m) = a - bm \quad (1)$$

where $N(m)$ is the cumulative number of events having magnitude larger than m occurring in a given time. The parameter a depends on the number of events in the selected time and region. The slope parameter b , also known as “ b -value,” provides an estimate of the ratio between the number of small and large events and is generally about one. It can be shown that, when the GR is assumed as recurrence relationship, the probability density function of magnitude is the exponential function $f(m) = e^{(\alpha - \beta m)}$ with $\alpha = a \ln 10$ and $\beta = b \ln 10$. As this function covers an infinite range of magnitude, from $-\infty$ to $+\infty$, for practical applications, a lower and upper bounded version is used, which requires the identification of both a minimum and a maximum magnitude value. The definition of the minimum magnitude depends on the catalog completeness, while the definition of the maximum magnitude is still an open question, and its quantification may play an important role in PSHA for the mitigation against very large and rare events.

The characteristic earthquake model is instead based on the assumption that individual faults and fault segments tend to generate similar size or characteristic earthquakes having a relatively narrow range of magnitudes near the maximum with frequency of occurrence larger than that predicted by simply extrapolating the GR (Schwartz and Coppersmith 1984). The resulting probability density function of magnitude to be used in the PSHA has a more complex formulation with respect to the exponential probability density function derived from the GR (Young and Coppersmith 1985).

Earthquake Recurrence,

Fig. 1 Definition of the variables generally used to analyze time distribution of earthquake occurrence (*upper panel*). Lower panels depict a schematic representation of a possible distribution of observed inter-event times together with the estimated probability density function (*pdf*) and the corresponding cumulative function (*cdf*) (see text for the definition of pdf and cdf)

One of the assumptions of the PSHAs, derived from the Reid (1910) theory, is that the seismicity is stationary; as a consequence, the recurrence relationships derived for the current available seismic catalog are valid also in the future. However, as mentioned above, this assumption may not be valid on the geological time scale, thus requiring models that account for nonstationary behavior. As a fully deterministic approach is not yet feasible, the solution is to refer to the earthquakes as the outcome of stochastic processes. In particular, the earthquake occurrence is regarded as *renewal process* (Cornell and Winterstain 1988) in five dimensions: time, magnitude, and location. It is obvious that, given this assumption, the physical processes governing rupture initiation, propagation, and stopping are neglected. On the other hand, real nature of the earthquake process is too complex to be modeled by using deterministic approaches.

In a renewal process, the times between subsequent events are considered independent and identically distributed random variables. This implies that the expected time till the next event does not depend on any of the details of the last event but its time of occurrence. Once the earthquake occurs, the renewal process resets from the beginning.

Although a complete statistical analysis of earthquakes should consider the distribution of all the five dimensions (i.e., time, magnitude, and location), the physical variable largely used to make statistical inferences is the inter-event time, $\Delta t_i = t_i - t_{i-1}$, i.e., the time between two

consecutive shocks. Statistical distribution of Δt_i is analyzed to determine if the observed seismicity can be modeled by using a specific function (Fig. 1).

For simplicity, the inter-event time, Δt , will be indicated as t throughout the text. Inspection of the distribution of the observed t may help to establish some features of the seismicity, such as the presence of any regularity in time and possibly the influence of different tectonic/physics factors that regulate the spatial occurrence of earthquakes. For example, a relatively large percentage of small values of inter-event times may suggest that, in the area under study, earthquakes tend to cluster in time and thus cannot be modeled as statistically independent events.

Formally, the inter-event time distribution is defined unambiguously by its probability density function $f(t)$ (pdf). By definition, the pdf has to be positive in the range of existence of the random variable and its integral under the whole space must be one. The integral between $t = 0$ and $t = T$ defines the cumulative density function $F(t)$ (cdf), while integral between $t = T$ and $t = +\infty$ defines the survivor function $S(t)$, which represents the probability that the system will survive beyond time T , i.e., at least time T will elapse between consecutive events. The cumulative and the survivor functions are defined, respectively, as

$$F(T) = P\{t \leq T\} = \int_0^T f(u) du \quad (2)$$

$$S(T) = P\{t > T\} = \int_T^{+\infty} f(u)du \quad (3)$$

where $F(t)$ is a monotone not-decreasing function and $\lim_{t \rightarrow 0} F(t) = 0$ and $\lim_{t \rightarrow \infty} F(t) = 1$. Recalling the properties of the pdf, it is easy to find that $S(t)$ is the complementary function of $F(t)$. An alternative characterization of the distribution of the random variable t , widely used in seismic hazard calculation, is the hazard function $h(t)$, which is defined as the instantaneous rate of occurrence of the events:

$$h(t) = \frac{f(t)}{1 - F(t)} = \frac{f(t)}{S(t)} \quad (4)$$

where the numerator expresses the conditional probability that the event will occur in the interval $(t; t + \delta t)$ given that it has not occurred before, and the denominator is the – infinitesimal – width of the interval. The hazard function is not a density or a probability function. However, we can think of $h(t)\delta t$ as the conditional probability of failure in an infinitesimally small time period between t and $t + \delta t$, given that the considered system has survived up till time t . The concept of the hazard function is borrowed from the analysis of failure of engineering systems. By analogy, earthquakes may be regarded as mechanical failures of rocks that resist to failure through friction and cohesion. There is a biunivocal relationship between probability density function, the cumulative function, the survivor function, and the hazard function; nevertheless, the hazard function is often preferred because a simple analysis of its trend can provide useful insights on the physics of the process under study. Moreover, it has two additional properties: it is additive for two independent subprocesses, and if no event occurs between t and $t + u$ and $v \geq u \geq 0$, then $h_t(v) = h_{t+u}(v-u)$ (Zhuang et al. 2012).

An increasing trend would stand for an increase in the probability of occurrence with the time elapsed since the last event. This case would support, in general, the seismic gap hypothesis, as well as any general model based on the “characteristic earthquake” with almost constant recurrence times. On the other hand, a

monotonic decreasing trend of the hazard function would stand for a “clustered” sequence, where the probability of occurrence decreases with the time elapsed since the last large event. A constant hazard function characterizes the Poisson process; in such case the conditional probability of having an earthquake in a fixed time interval is “time independent,” i.e., it is independent from the time elapsed since the last event.

As mentioned in the introduction section, earthquake rupture forecast aims at modeling the probability of occurrence of all possible damaging earthquakes in a given region during a specified time span. The functions defined so far provide the tools to reach the goal. Indeed, the requested probabilities are the conditional probabilities to have one or more earthquakes in the next τ years of interest, given a time t since the last event; this can be

$$P(T \leq t \leq T + \tau | t > T) = \frac{S(T) - S(T + \tau)}{S(T)} \quad (5)$$

where $S(T)$ is the survivor function. In practical applications the time scales of interest are generally shorter than the mean recurrence intervals of the major faults present in the area of interest. Thus, several values of τ are selected based on the aim for which the analysis is conceived. For example, the reference seismic hazard map of Italy has τ equals 50 years based on the assumption that this time corresponds to the average lifetime of a civil structure.

From the point of view of modeling the temporal behavior of earthquakes, the recurrence models can be divided in two main classes. The first class contains the “memoryless” model, i.e., the Poisson model, whereas the second class includes the non-Poissonian models, i.e., time-dependent models. While the Poisson model is extensively used in PSHAs, its adequacy is limited since the mechanism of earthquake interactions at regional scale has highlighted the tendency to a spatiotemporal clustering of earthquake occurrence, even for moderate earthquakes. Moreover, due to the “memoryless”

property, it is not adequate to model the occurrence of earthquakes on an individual fault where non-Poisson models perform better. In the following section, the most common statistical models for earthquake occurrence are described. Because of the intrinsic complexity of the problem of earthquake forecasting, in PSHA usually several models are used at the same time, the contributions of which are then weighted using a logic tree scheme. On one hand, this approach represents the scarce knowledge about earthquake occurrence process, and it is highlighted by the fact that, in some cases, antithetical models are simultaneously used. On the other hand, it is a way to contemplate the complexity of the earthquake occurrence, since different probability models incorporate different physical attributes of the earthquake process that a single statistical distribution could not incorporate. Generally speaking, in any model there may be two types of uncertainty: *aleatory uncertainty* and *epistemic uncertainty*. The *aleatory* uncertainty is associated to the intrinsic stochastic nature of the process resulting in an unavoidable impossibility of predicting deterministically its evolution. The *epistemic* uncertainty represents the limited knowledge of the system. To the extent that a process is knowable, in principle its epistemic uncertainty is reducible, while *aleatory* uncertainty is not. The inclusion of different models for earthquake forecasting, and the adoption of a logic tree scheme, is a way to quantify the epistemic uncertainty of the process.

Time-Independent Models

The Poisson Model

Because of its simplicity and small number of parameters to be estimated, the Poisson model has been long used to model seismicity, which, on different space and time scales, shows a high degree of randomness. Moreover, it is still one of the most used models in standard PSHA applications. The Poisson model provides a simple scheme for estimating the probability of occurrence of events governed by a Poisson process.

A counting process is said to be a Poisson process with rate λ , $\lambda > 0$, if it is characterized by:

- (i) *Stationarity*. The probability of an event in a short interval of time t to $t + h$ is approximately λh , for any t .

$$P\{N(h)=1\} = \lambda h + o(h) \quad (6)$$

- (ii) *Nonmultiplicity*. The probability of two or more events in a short interval of time is negligible compared to λh .

$$P\{N(h) \geq 2\} = o(h) \quad (7)$$

- (iii) *Independence*. The number of events in any interval of time is independent of the number in any other (nonoverlapping) interval of time. The process is thus said to be “memoryless.”

- (iv) The number of events in any interval of length t is Poisson distributed with mean λt . That is, for all $s, t \geq 0$,

$$P\{N(t+s) - N(t) = k\} = \frac{(\lambda s)^k e^{-\lambda s}}{k!} \quad (8)$$

for $k = 0, 1, 2, \dots; \lambda > 0$

where λ is the rate of occurrence of events, i.e., the number of events in unit of time.

Starting from (iv), it can be shown that, for a Poisson process, the inter-event times τ (or Δt) are exponentially distributed with cdf $F(\tau)$ and pdf $f(\tau)$ given by

$$F(\tau) = 1 - e^{-\lambda \tau} \quad \tau \geq 0, \lambda > 0 \quad (9)$$

$$f(\tau) = \lambda e^{-\lambda \tau} \quad \tau \geq 0, \lambda > 0 \quad (10)$$

Using Eqs. 9 and 10, it is possible to calculate the hazard function $h(\tau)$, which for the specific model is given by

$$h(\tau) = \frac{f(\tau)}{1 - F(\tau)} = \lambda \quad (11)$$

This result implies that the probability of occurrence of earthquakes in a future small increment

of time remains constant regardless of the elapsed time since its occurrence or the size of the last event (in case of spatial Poisson model).

The shape of the pdf and the hazard function for three different values of λ are shown in Fig. 2, panel a. As previously noted, the hazard function is a constant that depends only on the rate of occurrence of the events in the area under study or on the fault, i.e., the number of target earthquakes in the unit of time. Areas or faults with higher rate of occurrence have thus higher probability to experience the next earthquake, regardless the time occurred since the last one.

A direct generalization of the Poisson process is the *nonhomogeneous Poisson process*. As the regular Poisson process, it is based on the assumption of independent increments and at most one occurrence at any instant of time. Different from the homogeneous Poisson process, rate parameter λ depends on time, i.e., $\lambda(t)$. For a nonhomogeneous Poisson process, the probability of having n events in a given time interval (t_1, t_2) is given by

$$P[N(t_2) - N(t_1) = n] = \frac{\left[\int_{t_1}^{t_2} \lambda(u) du \right]^n}{n!} e^{-\left[\int_{t_1}^{t_2} \lambda(u) du \right]} \quad n = 0, 1, 2, \dots, \quad (12)$$

where $\lambda(t)$ is the instantaneous rate of occurrence and $\int_{t_1}^{t_2} \lambda(u) du$ is the expectation value over the considered time interval.

The inter-event time random variable for a set of events modeled as a nonhomogeneous Poisson process has the following cumulative distribution:

$$F(\tau) = 1 - e^{-\left[\int_0^\tau \lambda(u + t_s) du \right]} \quad \tau \geq 0 \quad (13)$$

where t_s is the time since the last event. Once the appropriate $\lambda(t)$ has been identified by analyzing

the observed data, the hazard function can be obtained noting that

$$h(\tau) = \frac{f(\tau)}{1 - F(\tau)} = \frac{d}{d\tau} \{-\ln[1 - F(\tau)]\} \quad \tau \geq 0 \quad (14)$$

As an example, this model has been applied by Reasenber (1985) to model aftershock sequences and formulate a declustering procedure for seismic catalogs. Concerning the $\lambda(t)$ function, Hong and Guo (1995) by analyzing the seismicity near Taiwan have demonstrated that a U-shaped function is more suited to model the occurrence of clustering earthquakes with respect to a constant rate or a monotonic increasing or decreasing function. The U-shaped function prescribes a constant hazard during the waiting period between cluster of events and higher values at times immediately after the last event or before the next sequence of events.

Time-Dependent Models

Unlike the time-independent models, in time-dependent models, the probability of occurrence of the next event (either in time or space) is modified by the features of the preceding events. In particular, a large class of statistical models assumes that the probability of future events may increase with elapsed time since the last earthquake and is in general applied to define the distribution of earthquakes on single faults. Moreover, for a fault that is in the early stage of the seismic cycle, these models prescribe a lower probability of occurrence compared to the Poisson model, whereas for faults in the late stage of the seismic cycle, they predict a higher probability of next event with respect to the Poisson model. Other models imply that earthquake occurrence probability is higher immediately after a previous event, and it decreases with the time elapsed; this behavior represents the clustered renewal models, and it is more suitable to represent the seismicity of extended areas, which enclose more than a single fault. In both cases, after the occurrence of each event at a

Earthquake Recurrence, Fig. 2 (continued)

Earthquake Recurrence, Fig. 2 Probability density functions and hazard rate functions for the Poisson model (panel a), the Weibull model (panel b), the gamma model (panel c), and the lognormal model

(panel d). In each panel, line colors refer to different combinations of the parameters that characterize the specific distribution

given time t , the system is brought back to the conditions it presented at the time of the last renewal (i.e., the system is perfectly renewed).

Early examples of time-dependent models applied to single fault as an alternative to the standard Poisson model are dating back to the 1970s (Bufe et al. 1977). Analyzing data relative to large thrust-fault earthquakes in Japan, Shimazaki and Nakata (1980) observed that the larger the coseismic slip displacement measured in an earthquake, the longer is the following quiet period. Based on simple assumptions about the initial stress τ_1 and the final stress τ_2 of faulting, the authors suggested two recurrence models known as *time-predictable* model and *slip-predictable* model. In the following, the main features of both models are described. Considering for simplicity that cyclic strain, which is accumulated in time with a constant rate due to tectonic processes is relieved on the same fault, then the stress drop $\Delta\tau$ is assumed to be proportional to the coseismic slip $\overline{\Delta u}$:

$$\Delta\tau \cong \mu \frac{\overline{\Delta u}}{L} \quad (15)$$

where μ is the shear modulus and L is a characteristic fault dimension. Now, if τ_1 and τ_2 are time

independent, then the sequence of earthquakes is a perfect periodic process, and the model is a *characteristic* recurrence model (Fig. 3a). On the other hand, when τ_1 or τ_2 or both are not constant, the process will be no longer periodic. In the assumption that fault strength is constant and that the fault will always rupture when the stress reaches the maximum stress capacity of the fault τ_1 (i.e., τ_1 is constant), if τ_2 is not constant, slip on the fault can vary with each event. Of course, greater slip releases more energy and the recurrence time (time between slip events) is longer because those stresses need to build up once again. This model is said to be *time predictable*, because knowing the amount of slip during the past earthquake, it allows prediction of the time of the next earthquake, but not its magnitude (Fig. 3b). Differently, suppose that τ_1 is not constant, that is, the fault does not rupture at the same stress level each time. If τ_2 is constant, each event reduces the stress on the fault to the same stress level. After an earthquake, stress on the fault will increase at a constant rate from τ_2 . The potential fault slip at any time is proportional to the shear stress on the fault. Thus, if the time of the last rupture is known, the shear stress on the fault and the potential displacement can be determined at any

Earthquake Recurrence, Fig. 3 Earthquake occurrence models. For each model, the upper panels show the stress pattern during different seismic cycles, while the lower panels show the corresponding structure of fault slip. (a) Perfectly periodic model of constant stress increase to a certain level (τ_1) and constant stress drop back to a certain

level during the earthquake (τ_2). (b) Time-predictable model illustrating stress buildup to a certain level and nonuniform stress drops. (c) Slip-predictable model showing nonuniform stress buildups and stress drops to a certain level

particular time of interest. This model is said to be *slip predictable*, in that, it cannot be used to predict when rupture will occur, but it can be used to predict the magnitude of the earthquake that would occur at any given time (Fig. 3c). The application of these models to earthquake forecast has encountered criticism in the seismological community. As an example, Mulargia and Gasperini (1995) have tested the two models on the Italian seismic catalog and found no significant correlation between the coseismic slip of an event and that previous or subsequent inter-event time.

In the following, the most common applied statistical models to model earthquake occurrence are described.

Weibull Model

One of the first applications of the Weibull distribution in geosciences is the one proposed by Hagiwara (1974). Based on the assumption that the Earth crust is strained with a constant speed, he modeled crustal-rupture occurrence time of the South Kanto District in Japan by using the Weibull model. The same distribution was also used by Rikitake (1976) to model the recurrence

times of great earthquakes at the Pacific subduction margins. The formula for the probability density function of the general Weibull distribution is

$$f(t) = \frac{\beta}{\alpha} \left(\frac{t - \mu}{\alpha} \right)^{\beta-1} e^{-\left(\frac{t - \mu}{\alpha} \right)^\beta} \text{ for } t \geq \mu; \beta, \alpha > 0 \quad (16)$$

where β is the shape parameter, μ is the location parameter, and α is the scale parameter. When $\mu = 0$ and $\alpha = 1$, the distribution is called the standard Weibull distribution. The case where $\mu = 0$ is called the 2-parameter Weibull distribution which is generally used for seismological applications. For the 2-parameter distribution, the corresponding cdf and the hazard function are defined as follows, respectively:

$$F(t) = 1 - e^{-\left(\frac{t}{\alpha} \right)^\beta} \quad (17)$$

$$h(t) = \frac{\beta}{\alpha} \left(\frac{t}{\alpha} \right)^{\beta-1} \quad (18)$$

Equations 16, 17, and 18 show that the shape parameter β has a marked effect on the shape of

the functions. However, some interesting insights can be drawn from the analysis of the hazard function (Eq. 18) as shown in Fig. 2b, in which the pdf and the hazard functions are displayed for three different values of β (i.e., 0.5, 1.0, and 2.0) and an α value of 3.0. Indeed, if the inter-event time distribution has a Weibull best-fit model, then the value of β can be used to depict some features of the analyzed seismicity. If, for example, β is equal to 1, the pdf reduces to an exponential function with constant hazard function and rate equal to $1/\alpha$; the process is thus a random process. If $\beta < 1$, then the system exhibits early-type failures, with a decreasing hazard function, with time elapsing since the most recent event, while for $\beta > 1$ the system exhibits wear-out type failures, with an increasing hazard function. The analog for the earthquake generation process for $\beta < 1$ is a clustering property of the earthquake occurrence, while for $\beta > 1$ the pdf can be approximated by a Gaussian or normal distributions and the events, based on the value of α , are quasiperiodic in time.

Gamma Model

Modeling of nonindependent events through a gamma distribution was first presented by Udias and Rice (1975) in their analysis of microearthquake activity near San Andreas Fault, California. Looking at the distribution of the inter-event times, they observed a maximum amount of low values of inter-time intervals and a higher number of events with respect to that predicted by a Poisson model. The deviation from a simple Poisson model was ascribed to a clustering property of the seismicity. The authors thus proposed to fit the observed distribution of the inter-event times by using the gamma distribution. The gamma distribution is a two-parameter function and for $t \geq 0$ the formulation of the pdf is as follows:

$$f(t) = \frac{t^{\alpha-1} e^{-t/\beta}}{\beta^\alpha \Gamma(\alpha)} \quad \text{for } \alpha > 0, \beta > 0 \quad (19)$$

In the above equation, β is a scale parameter reflecting the units of measure, while α controls the shape of the distribution. The gamma

distribution allows to combine a power law, which is usually used to model short inter-event times, that is, clustered events, and long inter-event times through the exponential function which is typical of Poisson seismicity. The corresponding cdf is

$$F(t) = \frac{\gamma(\alpha, t/\beta)}{\Gamma(\alpha)} \quad (20)$$

where

$$\Gamma(\alpha) = \int_0^\infty u^{\alpha-1} e^{-u} du \quad \gamma(\alpha, t) = \int_0^t u^{\alpha-1} e^{-u} du \quad (21)$$

while the hazard function is given by

$$h(t) = \frac{t^{\alpha-1} e^{-t/\beta}}{\beta^\alpha (\Gamma(\alpha) - \gamma(\alpha, t))} \quad (22)$$

It can be shown (e.g., Denker and Woyczynski 1998) that the parameters α and β are related to the mean and the variance of the empirical distribution of the inter-event times. In particular, $\alpha \cdot \beta = \mu$ and $\alpha \cdot \beta^2 = \sigma^2$ where μ and σ^2 are the mean and the variance of the observed distribution, respectively. Figure 2c shows the pdf and the hazard function for the gamma distribution for different values of α (i.e., 0.5, 1.0, and 2.0) and a β value of 2.0. From the earthquake occurrence point of view, the α -parameter is the regularity parameter, while beta-parameter is the time scaling parameter. When α is less than 1, the process is clustered; when $\alpha = 1$, the process is Poisson, neither clustered nor regular (the distribution is the exponential distribution, with constant hazard function equals $1/\beta$); and when $\alpha > 1$, the process tends to regular. For large values of α (let us say larger than 100), the inter-event time is almost fixed.

Lognormal Model

Nishenko and Buland (1987) found that normalized earthquake recurrence intervals, for large earthquakes in the circum-Pacific region, along

specific faults or plate boundary segments, can be described by a lognormal distribution. Combining both historic and geologic recurrence data, the authors found that the lognormal distribution fits the observed data significantly better than either the Gaussian or the Weibull distributions.

Since the study by Nishenko and Buland (1987), it has become common practice to use the lognormal distribution in several applications in seismology. One of the most relevant was in computing earthquake probabilities in California (Working Group on California Earthquake Probabilities 2007 and previous works) and for time-dependent seismic hazard analysis (e.g., Cramer et al. 2000).

The pdf of the distribution is given by the equation:

$$f(t) = \frac{1}{\sqrt{2\pi} \sigma_{\ln T} t} e^{-\frac{(\ln t - \mu)^2}{2\sigma_{\ln T}^2}} \quad (23)$$

where $\sigma_{\ln T}$ is the standard error deviation of the logarithm of the recurrence time. The corresponding cdf and the hazard function $h(t)$ have the following expression:

$$F(t) = \frac{1}{2} + \frac{1}{2} \operatorname{erf} \left(\frac{\ln t - \mu}{\sqrt{2\sigma_{\ln T}^2}} \right) \quad (24)$$

$$h(t) = 2 \left[\sqrt{2\pi} \sigma_{\ln T} t \left(1 - \operatorname{erf} \left(\frac{\ln t - \mu}{\sqrt{2\sigma_{\ln T}^2}} \right) \right) \right]^{-1} e^{-\frac{(\ln t - \mu)^2}{2\sigma_{\ln T}^2}} \quad (25)$$

One of the main features of the lognormal distribution is that it is a heavy-tailed distribution, that is, there is a larger probability of getting next earthquakes with respect to the exponential function for the same time window. This feature makes the distribution suitable for fitting inter-arrival times of those events whose return period is larger than the average return period. This is visually explained in Fig. 2d, where the pdfs and the hazard functions for $\mu = 0$ and three different values of $\sigma_{\ln T}$ (e.g., 0.5, 1.0, and 1.5) are shown. The pdfs are peaked, and the

hazard functions have zero value $t = 0$, i.e., the probability of having an earthquake is zero at the beginning of the cycle, then they reach their maximum, and finally decrease asymptotically to zero.

Brownian Passage-Time Model

Brownian passage-time model (BPT model hereinafter) has been developed by Matthews and coworkers in the early 2000s in the framework of earthquake forecasting. The aim was to make a connection between the rebound theory, with the main characteristics of the stress and strain accumulation process, and the observable distribution of the real inter-event data and build up a physically motivated renewal model for earthquake recurrence (Ellsworth et al. 1999; Matthews et al. 2002). In BPT model, the constant tectonic loading is superimposed by a Brownian perturbation, which makes the stress loading a Brownian relaxation oscillator (BRO). The Brownian perturbation could be interpreted as a physical representation of the interaction of external perturbation of the cycling stress load of a fault. In the BRO model, a new earthquake will occur when a state variable (or a set of them) reaches a threshold (X_p); it relaxes the load state to the characteristic ground level (X_0) and begins a new cycle (panel a in Fig. 4).

In the BPT model, the loading of a fault is the composition of two elements: a constant-rate loading component, λt , and a random component, $\epsilon(t) = \sigma W(t)$, as a Brownian motion (where $W(t)$ is a standard Brownian motion and σ is the non-negative scale parameter). Standard Brownian motion is simply the integration of stationary increments where the distribution of the increments is Gaussian (which might be motivated by central-limit arguments if the perturbations are considered as the sum of many small, independent contributions), with zero mean and constant variance:

$$X(t) = \lambda t + \sigma W(t) \quad (26)$$

The BRO model belongs to the family of stochastic renewal processes identified by four

Earthquake Recurrence, Fig. 4 Panel (a) shows three examples of loading state variable trend for the three different aperiodicity values indicated in the inset of panel (b). The levels indicated possible values of the

ground state X_0 and the failure state X_f , respectively. Panel (b) shows the pdf and the hazard rate as a function of three different aperiodicity values

parameters: the mean loading (drift) rate (λ), the perturbation rate (σ^2), the ground state (X_0), and the failure state (X_f). The recurrence properties of the BRO (repose times) are described by a Brownian passage-time distribution which is characterized by two parameters: the mean time or period between events (μ) and the aperiodicity of the mean time (α) which is equivalent to the coefficient of variation ($\alpha = \sigma/\mu$). The probability density function for the BPT model is given by

$$f(t; \mu, \alpha) = \left(\frac{\mu}{2\pi\alpha^2 t^3} \right)^{1/2} e^{-\frac{(t-\mu)^2}{2\mu\alpha^2 t}} \quad (27)$$

The cumulative distribution is

$$F(t) \triangleq P\{T \leq t\} = \Phi[u_1(t)] + e^{2/\alpha^2} \Phi[-u_2(t)] \quad (28)$$

where $\Phi(t)$ is the cumulative Gaussian probability function, u_1 and u_2 are defined as follows:

$$u_1 = \alpha^{-1} [t^{1/2} \mu^{-1/2} - t^{-1/2} \mu^{1/2}] \quad (29)$$

$$u_2 = \alpha^{-1} [t^{1/2} \mu^{-1/2} + t^{-1/2} \mu^{1/2}] \quad (30)$$

and the first moment is $E(T) = \mu$ with $\text{var}(T) = (\mu\alpha)^2$. The mean inter-event gauges the typical frequency at which events occur, and in BPT parameterization it is the scale parameter (i.e., changing μ , the distribution is rescaled in time but its shape is not altered). The aperiodicity is the shape parameter of the BPT family; it is a dimensionless measure of irregularity in the event sequence, and it modifies the shape of the distribution, from a perfectly periodic sequence with $\alpha = 0$ to a random process with an increasing α . As an example panel a in Fig. 4 shows the shape of the pdf and the hazard function for three different values of the aperiodicity parameter α , when μ is set to one.

Compared to the other statistical distributions proposed so far, the $h(t)$ of a BPT distribution is always zero at $t = 0$ (see panel b in Fig. 4), and this implies that after an earthquake the cycle is returned to its starting state and the probability of having a new earthquake is zero; it increases to achieve its unique maximum value at some finite time to the right of the density's mode, and from there it decreases asymptotically at level $h_\infty = (2\mu\alpha^2)^{-1}$ (panel b in Fig. 4). This last property is very important, since it implies that a long time after the previous event, the probability of having a new one does not depend any more from the time since the last event, but it is a constant that depends on the propriety of the fault (i.e., it depends on the mean of the distribution and its aperiodicity $(2\mu\alpha^2)^{-1}$).

It is important to notice that the five models proposed so far imply different mechanisms for earthquake occurrence. All but Poisson model are applied to mark the occurrence of large earthquakes on faults, while the Poisson model can also be used to model the seismicity into homogeneous seismotectonic zonation, where each single zone includes several faults. Trigger models described in the next section are applied on extended areas, where the interaction among faults plays an important role and the clustering of the seismicity is the main feature in

earthquake occurrence, at least in the short time after the most recent event.

To compare the statistical and physical proprieties of the models, their behavior soon after the last event (i.e., at the beginning of the cycle) and after a long time since the last event is analyzed. At $t = 0$, lognormal distribution, BTP, gamma, and Weibull distributions with shape parameters larger than 1 have zero probability of occurrence of next earthquakes. This is conceptually in agreement with the interpretation of the elastic rebound theory and implies that after a large earthquake, the fault is unloaded at its ground level. The lognormal distribution and the BPT remain with lower values of the pdf in the first part of the main recurrence interval, while gamma and Weibull have steep increases, and the probability of new events increases rapidly with time. For the gamma and Weibull distributions with shape parameters less than 1, at $t = 0$ the probability of having a new event is high, indicating a clustering behavior of the seismicity, and for shape parameters equal to 1, they behave as a time-independent Poisson model. All functions are unimodal, with the mode located on the left of the mean of the distributions, implying that most of the events occur at times less than the average time of occurrence.

After long time since the most recent event, the behavior of the distributions can be divided into three classes, except for the case of time-independent distribution. In one case the hazard function reaches a constant value, in the second it goes to zero, and only for the Weibull distribution with shape parameter larger than 1 it grows theoretically to infinity. The important point that should be emphasized in this encyclopedia is the implication that these characteristics have in the definition of the probability of occurrence of earthquakes. The hazard function reaches zero as time goes to infinity for the lognormal distribution and the Weibull distribution with shape parameter less than 1. According to some researches, this characteristic disqualifies these distributions as reliable models, especially if the mechanism of earthquake occurrence is contextualized within the process of steadily increasing load on fault. Some other researchers point out that the stress can likely be dissipated by

alternative mechanisms (seismic or aseismic) and not through the occurrence of the event, and so a decreased failure rate may be appropriate. On the contrary, models with hazard function reaching a constant value as time goes to infinity, as for the BPT and the gamma distribution, imply that after the time corresponding to the mean recurrent interval is passed, the distributions become “time independent,” and the time since the most recent event does not influence any more the occurrence of the next event. The only factors able to control the earthquake occurrence are in the model parameters, as, for example, the mean and the aperiodicity of the BPT distribution.

Trigger Models

One of the most important characteristics of the earthquake time series, which must be considered in the models of recurrence, is the tendency of the events to clustering. A possible definition of cluster is a set of earthquakes originating from a relatively small seismogenic volume and separated in time by very small intervals. Thus, the model should contemplate a finite probability of more than one event to occur in a given time increment. This feature is not taken into account by the Poisson process. A possible solution, which allows for events grouping, is the use of a compound Poisson process. This process permits that groups of independent and identically distributed events occur together at the instants of a simple Poisson process. However, the compound Poisson process may be not satisfactory because groups of events tend to spread or to diffuse over space and time. As an alternative class of models, those named trigger models have been proposed by Vere-Jones and Davies (1966). Basically, the models assume that events initiating groups of shocks – triggering events – occur by following a Poisson process with a constant rate, while the number of events in each group decays by following a prescribed function.

Generalized Poisson Model

In the framework of the trigger models, Shlien and Toksöz (1970) proposed to model the

seismicity contained in the United States Coast and Geodetic Survey (USCGS) catalog from 1961 to 1968, by using the generalized Poisson model. Assuming that cluster occurrence is governed by a Poisson process and that in each cluster the number of subsequent earthquakes follows a negative power law distribution, Shlien and Toksöz (1970) provided a recursive relation to compute the distribution of the number of days with n earthquakes based on two main parameters named k' and E . The probability distribution has the following formulation:

$$p_q(n+1, t) = \frac{kt}{n+1} \sum_{j=0}^n (n-j+1) q(n-j+1) p_q(j, t) \quad (31)$$

where $q(n)$ is the selected negative power law distribution also known as the Pareto distribution, given by

$$q(n) = \frac{1}{\zeta(E)} n^{-E} \quad (32)$$

where the normalization factor $\zeta(E)$ is the Riemann Z function.

The k' parameter controls the mean rate of cluster occurrence. The parameter E is a measure of the departure from the simple Poisson process. For large value of E (let us say larger than 5), the generalized Poisson model tends to a simple Poisson distribution. Figure 5 shows the shape of the pdf for $k' = 1$ and three different values of E (i.e., 2.0, 3.0, and 4.0). In the same figure, the right panel shows the hazard function obtained by numerical integration of the pdf for the same values of the two parameters. Among the several applications, the generalized Poisson model has been also used to model earthquake sequences and compute seismic hazard in volcanic contexts (De Natale and Zollo 1986; Convertito and Zollo 2011).

The ETAS Model

The spatiotemporal clustering of small-to-moderate size seismicity is a concept worldwide accepted in seismology. Among the few

Earthquake Recurrence, Fig. 5 Probability density function and hazard rate function for the generalized Poisson model. The selected values of the parameters k' and E are reported in the inset of the right panel

spatiotemporal models proposed in literature, the epidemic type aftershock sequence (ETAS) model is by far the most studied and applied, and, in some cases, it has been defined as the best way to describe short-term seismicity (Console et al. 2007; Zhuang et al. 2011, 2011) since its formulation in 1988 by Ogata (1988). ETAS model is grounded on empirical statistics and represents a stochastic implementation of the physically based model of Dieterich (1994), based on the interaction among faults. It assumes that there is no difference in triggering seismicity among foreshocks, mainshocks, and aftershocks, and event triggers its own offspring independently according to some probability rules. The hazard rate of the ETAS model is defined as

$$\lambda(t) = \mu + K_0 \sum_{t_i < t} \frac{e^{\alpha(m-m_0)}}{(t-t_i+c)^p} \quad (33)$$

where μ is the background rate (unit of time) of the seismicity and m_0 is the magnitude of completeness of the seismic catalog. The parameter α is a measure of the efficiency of a shock in generating an aftershock activity and it is relative to its magnitude; K_0 represents the productivity of an event of threshold magnitude m_0 , whereas c and p are parameters

of the Omori-Utsu law, which describes the temporal behavior the aftershock sequence. The 5 parameters of the ETAS model are generally estimated by using a maximum likelihood procedure. In literature, different parameterizations of the ETAS model are available, especially when also spatial distribution of the events is taken into account. For the purpose of this encyclopedia, the main features common to the ETAS models developed by different researchers are summarized in five points (Zhuang et al. 2011):

- The rate of background events is assumed to be a function of space and magnitude; the background events are generated following a specific pdf function (e.g., Poisson, BPT, etc.), and so they are considered as “immigrants” in the branching process.
- Each event produces direct offspring events independently of the others, and the productivity depends on its magnitude.
- The pdf of the time until the appearance of a child is a function only of the elapsed time since its parents.
- The pdf of the location and magnitude of children are a function of the location and magnitudes of the parents.

- Magnitude, of both offspring and background events, is a random variable, with a certain distribution, the most common of which is the Gutenberg-Richter relation.

ETAS model is widely adopted in short-term hazard studies, for its ability in the forecasting of aftershock sequence; also, it is adopted as declustering method for separating the background seismicity to the triggered one (Zhuang et al. 2002, 2004). Moreover, it has been found that the inclusion of a more realistic behavior of the seismicity in the temporal parameterization of earthquake occurrence in PSHA, with the well-known structure of the sequence, provides an increment of almost 10 % in the hazard, in low seismicity area, where the identification of active faults or background seismicity is trivial (Faenza et al. 2007).

Estimation of Parameters

It is worth noting that the models described in this entry may fit the available data set collected in the region under study equally well. This is especially true in case of large earthquakes, where the amount of data available may be not sufficient to test any hypotheses due to the limited time extent of the available seismic catalog. Before performing the parameter estimation, the completeness of the catalog has to be determined. This could be trivial in case of historical earthquakes; an erroneous evaluation of the completeness can affect the value of the model parameters and their uncertainties. It must be reminded that large events are rare, especially in area of moderate seismicity, and therefore a larger part of the seismic catalog are derived from pre-instrumental time.

In practical applications, the maximum likelihood estimate (MLE) is by far the most used technique to evaluate the parameter's models. The MLE is based on the use of the likelihood function L for the estimation of parameters. The L function represents the joint probability density of the analyzed variable, for example, the waiting times or the inter-arrival times. Given N data points and a model whose parameters are

identified by a vector θ , the best model parameters $\hat{\theta}$ are those maximizing the L function:

$$\hat{\theta} = \max_{\theta} L(N; \theta) \quad (34)$$

Generally speaking, the MLE method maximizes the agreement of the selected model with the observed data.

When several competing models are used to fit the same data set, the best model can be discriminated by using the Akaike information criterion (AIC), which uses the following statistic to evaluate the fitting performance of each model:

$$AIC = -2 \max_{\theta} \log L(\theta) + 2N_p \quad (35)$$

where N_p is the number of parameters involved in each investigated model. The model with the lowest AIC value is identified as the optimal model. AIC balances between the goodness of fit of the model and its complexity, and it provides penalties to models with a lot of numbers of parameters, to discourage overfitting. AIC does not provide a test of the model in absolute sense, but provides only a tool for the comparison of different models; if all models have poor fitting, AIC will not give any warning of it.

The residual analysis allows the evaluation of the degree at which the adopted model fits the data. The analysis uses a transformation to map general event times, in times having the same properties as homogeneous Poisson time with unit rate parameter (Zhuang et al. 2012). Thus, comparing the observed seismic rate with that obtained in the transformed time domain allows to evaluate the quality of the fit. The comparison allows also to recognize periods of decreased or increased seismic activity (Ogata 1988; Zhuang et al. 2012).

Summary

Seismic hazard in earthquake-prone regions can be expressed in several forms. The exceedance of a given ground-motion threshold value or the probability of having a given number of future

earthquakes that can affect a specific structure is of primary interest in seismic engineering. As a consequence, being able to model present and past seismicity that occurred in the area under study may be essential to make reliable forecast.

In this framework, the present work discusses the basic assumptions and the origin of the main statistical models used in the literature to fit the observed seismicity. Among the five dimensions which concur to basically characterize the earthquakes (i.e., time, magnitude, and location in 3D space), the physical observable of interest for statistical modeling is the earthquake recurrence, which is the time between subsequent events. In this respect, earthquakes are considered as specific stochastic processes named *renewal process* (Cornell and Winterstain 1988) in which after the occurrence of an event, the system process restarts from the beginning (i.e., is completely renewed).

The models used to describe the recurrence of the earthquakes can be divided in two main classes: the “memoryless” model, i.e., Poisson model, and the time-dependent models. While Poisson model is extensively used in PSHAs, its adequacy is limited since the mechanism of earthquake interactions at regional scale has highlighted the tendency to a spatiotemporal clustering of earthquake occurrence, even for moderate earthquakes. Moreover, due to the “memoryless” property, it is not adequate to model the occurrence of earthquakes on single faults in which case non-Poisson models perform better.

As a consequence, since the work of Bufe et al. (1977), a suite of models able to account for earthquake interaction and clustering has been introduced. We have presented those most used in practical applications such as Weibull, gamma, and lognormal and described their main features and differences in terms of their probability density functions and hazard functions. In addition we described a more physical model, that is, the Brownian passage time, which is currently used to perform time-dependent seismic hazard analysis in several areas, tectonic and volcanic areas such as California and Italy.

Finally we have discussed the generalized Poisson model and the ETAS model which, in addition to model single large-to-moderate events, allow to account for sequences of events clustering in time and space.

As previously mentioned, the selection of “the best model” among several competitors is not straightforward. In general, dealing with large earthquakes implies working with small numbers of data available for the fitting; this is especially true in case of recurrence on single fault or in area with moderate seismicity. In this perspective, in recent years, the seismological community has developed rigorous and truly perspective forecast experiments, as, for example, the CSEP experiment – Collaboratory for the Study of Earthquake Predictability, for different regions worldwide.

Earthquake Recurrence Law and the Weibull Distribution, Fig. 1

The observed frequency and the Poisson frequency of $M > 7.0$ earthquakes around Taiwan since 1978; this statistical study offered a tangible support to the use of the Poisson distribution in modeling the earthquake's randomness in time (Wang et al. 2014)

Introduction

Earthquakes are unpredictable given the difficulty of measuring the stresses and strains on a fault plane (Geller et al. 1997). The situation reflects the reality that recent catastrophic events went unpredicted, such as the 2008 Wenchuan earthquake in China and the 2011 Japan earthquake. Under the circumstances, a few alternatives for earthquake hazard mitigation are developed and practiced, including earthquake early warning, seismic hazard analysis, and earthquake statistics analysis (e.g., Hsiao et al. 2011; Chen et al. 2013; Wang et al. 2011, 2012a, b; Wu and Kanamori 2008).

With statistical models, earthquake probability can be best estimated accounting for the inevitable earthquake uncertainty in nature. One of the famous examples is the use of the Poisson model to estimate the earthquake probability with time. However, besides the support from mainly engineering judgments (earthquakes are rare), more tangible support was not available until a recent statistical study analyzed the seismicity around Taiwan since 1900 (Wang et al. 2014). That study carried out a series of statistical goodness-of-fit tests and indicated that the observed earthquake distribution showed a good agreement with the Poisson distribution. Figure 1 shows an instance from that study providing the

comparison between observation and simulation based on the earthquake data around Taiwan since 1900.

In addition to the modeling of the earthquake temporal uncertainty, some suggestions were proposed to model the probabilistic distribution of earthquake size, including the use of a specific “M-A” algorithm proposed by McGuire and Arabasz (1990), governed by the b -value of the Gutenberg-Richter (G-R) recurrence law:

$$\Pr(m_1 \leq M < m_2 | m_0, m_{\max}) = \frac{10^{-bm_1} - 10^{-bm_2}}{10^{-bm_0} - 10^{-bm_{\max}}} \quad (1)$$

where m_0 and $m_{\max}$ are the magnitude threshold and the maximum magnitude, respectively. With the algorithm, for instance, Fig. 2 shows the b -value of 0.92 from the G-R relationship given the seismicity in Taiwan since 1900. Based on the b -value, Fig. 3 shows the modeling of the earthquake-size probability distribution around Taiwan with the M-A algorithm expressed in Eq. 1. It shows that this approach overall offers a satisfactory fit to the earthquake observations, although the model could not capture the probability at lower magnitudes. One of the reasons causing this problem could be the “de-log” process involved in the calculation. That is, as shown in Fig. 2, the b -value calibrated is on the basis of

Earthquake Recurrence Law and the Weibull Distribution, Fig. 2

The G-R recurrence law for the seismicity around Taiwan since 1900; the b -value, the slope $\times -1$ in such a dimension, was found around 0.92

Earthquake Recurrence Law and the Weibull Distribution, Fig. 3

Observed earthquake-size distribution given $M_L > 3.0$ events in Taiwan since 1900; given the b -value of 0.92, the plot also shows the simulated earthquake-size distribution with a specific M-A algorithm expressed with Eq. 1

a logarithmic scale, rather than in the arithmetic scale used to present the earthquake-size probability or frequency.

Therefore, in this technical note another option for the earthquake analysis is introduced. Different from the existing approach previously mentioned, the alternative is an application of the Weibull distribution to earthquake statistical studies. The details of the methodology and a case are given in the following.

The Probability Density Function of Earthquake Size Around Taiwan

As shown in Fig. 3, the probability density function for earthquake size was extracted from a catalog listing the earthquakes around Taiwan since 1900 (Wang et al. 2011, 2012a). For example, above all M_L 3.0 (local magnitude) earthquakes, the probability density for earthquakes larger than 7.0 is around 0.01 % among the total

of 55,000 events. In addition, the data also show that the earthquake-size probability distribution is nonlinear and asymmetrical, with the frequency or density decreasing rapidly as magnitudes increase. Therefore, an asymmetrical probability model such as the Weibull distribution should have more potential to model such an earthquake statistic, than symmetrical distributions like the normal distribution.

The Probability Function of the Weibull Distribution

The probability density function (PDF) of the Weibull distribution is expressed as follows (Devore 2008):

$$f(x; \alpha, \beta) = \begin{cases} \frac{\alpha}{\beta} x^{\alpha-1} e - (x/\beta)^\alpha & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (2)$$

where α and β are the model parameters, which can be calibrated with the mean (i.e., μ_X) and SD (i.e., σ_X) of X . The relations between μ_X , σ_X , α , and β are as follows:

$$\mu_X = \beta \Gamma\left(1 + \frac{1}{\alpha}\right) \quad (3)$$

$$\sigma_X^2 = \beta^2 \left(\Gamma\left(1 + \frac{2}{\alpha}\right) - \left[\Gamma\left(1 + \frac{1}{\alpha}\right) \right]^2 \right) \quad (4)$$

where $\Gamma()$ denotes the gamma function:

$$\Gamma(a) = \int_0^{\infty} x^{a-1} e^{-x} dx \quad (5)$$

Therefore, given the mean and SD from observations or samples, α and β of the Weibull distribution can be calibrated with Eqs. 3 and 4. Afterward, the corresponding Weibull distribution can be developed for modeling earthquake-size distributions. However, although this is a two-equation-two-unknown problem, the analytical solution of α and β could be fairly challenging to be developed for such a mathematical

problem with the involvement of the gamma function. As a result, an in-house optimization procedure was developed for the task, and it was introduced in the following section for the reader's information.

Model Parameter Calibrations

Since the solution could be difficult to be developed analytically, a numerical procedure to calculate α and β was developed and the details were given in the following. Using the first given information (i.e., μ_X), from Eq. 3 the relationship between α and β can be rewritten as follows:

$$\beta = \frac{\Gamma\left(1 + \frac{1}{\alpha}\right)}{\mu_X} \quad (6)$$

With this relationship, the calibration can be followed by a trial-and-error process by varying the value of α (so β changes as well) and substituting both into Eq. 4 to calculate the variance of X . As a result, the absolute difference, $D = f(\alpha)$, between the calculated variance and given variance (i.e., the second given information) in each trial can be calculated.

With the preliminary analysis showing the change in D given different α values, it was found that this variable would converge with the increase of α from a nominal value near zero (α cannot be zero; see Eq. 4) to the solution of α . Therefore, the searching process will be stopped when $D_{i+1} = f(\alpha_i + \Delta\alpha)$ is greater than $D_i = f(\alpha_i)$. For a better resolution in results, a smaller increment of α can be used, say, 0.005.

Apparently, this numerical solution is a computer-based procedure, and the tedious iteration should be complete with computers in a fraction of time. Therefore, this algorithm proposed was programmed into two user-defined functions for Excel. Note that the two functions are nearly identical except for returning α or β at the end. For example, the syntax of the function to calibrate α was created as follows: WEIBULL _ AFA(mn , sd), and obviously

Earthquake Recurrence Law and the Weibull Distribution, Fig. 4 The comparison between the observed earthquake-size distribution and the Weibull distribution with $\alpha = 1.11$ and $\beta = 0.46$ calibrated with the observed mean and standard deviation in the randomness of

earthquake size; this statistical analysis indicated that the Weibull distribution should be suitable to the modeling of earthquake-size distributions based on the empirical finding with earthquake data from Taiwan

“*mn*” and “*sd*” are the function input, standing for the mean and standard deviation of the random variable, respectively. The complete VBA (Visual Basic for Application) scripts of the function are given in the Appendix for the reader’s information.

The in-house function was subject to verification before it was used in the following statistical analysis. The first attempt is to calibrate α and β given $\mu = 10$ and $\sigma = 1$. With the in-house tool, α and β were computed at 12.16 and 10.43, respectively. Substituting them back into Eqs. 3 and 4, μ and σ were found equal to 10 and 0.999, which matched the given values almost perfectly. The second attempt is to test the function’s reliability under a large-variability condition with the standard deviation increased from 1 to 50. Given $\mu = 10$ and $\sigma = 50$, the corresponding α and β are equal to 0.31 and 0.25, respectively. Again substituting both into Eqs. 3 and 4, μ and σ were computed at 10 and 50.45, also close enough to the given conditions. As a result, after two verifications the in-house algorithm and user-defined function were proved reliable and functional.

Case Study with Earthquake Data Around Taiwan

As shown in Fig. 3, given magnitude threshold = 3.0, the mean earthquake size and standard deviation from about 55,000 earthquakes in Taiwan are equal to 3.442 and 0.398, respectively. With Eqs. 3 and 4, α and β of the Weibull distribution are 1.11 and 0.46, respectively. It must be noted that such a calculation was performed on the basis of shifted data, because the Weibull distribution is about the modeling of a random variable ranging from zero to infinity. As a result, the α and β values calibrated are corresponding to the shifted data with mean = 0.442 and SD = 0.398. (The shifted data are the original data subtracting the magnitude threshold of 3.0.) Note that because the variability of data is not affected by data shifting, the SD used for calibrating α and β values is the same as the original SD.

With the model parameters calibrated from observations, Fig. 4 shows both the observed earthquake-size probability density and the

modeling with the Weibull distribution. This analysis indicated that the earthquake-size distribution in Taiwan shows a good agreement with the Weibull distribution.

Discussions

Applications and Verifications with Seismicity in Different Regions

The statistical study of this note offered tangible evidence about the earthquake size's randomness potentially following the Weibull distribution, with the earthquake data around Taiwan since 1978. Although it is believed that this statistical finding should be generic and could be applied to seismicity of different region, more earthquake statistics studies are necessary to provide more support or disagreement on this empirical finding: the earthquake-size distribution follows the Weibull distribution.

Curve-Fitting Parameters

Like the G-R relationship, the new earthquake model on the basis of the Weibull distribution is an empirical relation, without physical indications to why the earthquake's size should be a random variable following such a mathematical function. In other words, the model parameters (i.e., α and β) hold no physical explanations or meanings to earthquake mechanisms, although this statistical model provide a very satisfactory fit to the earthquake data around Taiwan. After all, it was still a statistical study or curve fitting, which was not an analytical study derived with basic laws of physics.

Summary

This entry presents a statistical study regarding earthquake-size distributions in Taiwan since 1978. From earthquake observations, the probability density of earthquake size was found highly asymmetrical, with the majority of seismicity being small earthquakes. This asymmetrical observation motivated the use of the Weibull distribution in an attempt to model the data and

to see if it could provide a reasonable fit to the randomness of earthquake size observed in Taiwan.

With such a statistical study, it was found that the Weibull distribution could fit the earthquake data in Taiwan reasonably well. For instance, given a magnitude threshold of 3.0, mean magnitude of 3.442, and standard deviation of 0.398, the corresponding parameters α and β of the Weibull distribution are 1.11 and 0.46, respectively. With the parameters calibrated with the seismicity, the observation and the model are in a satisfactory agreement in earthquake-size distribution.

Although this statistical study suggests a possible relationship between earthquake size and the Weibull distribution, this empirical finding offers no explanation to earthquake mechanisms and to why the earthquake's size distribution should follow the specific mathematical function. In other words, the Weibull distribution could be useful and reliable for modeling the earthquake-size probability distribution from a statistical point of view, but the model itself offers no explanation to the underlying earthquake mechanics.

Appendix: VBA Scripts of the In-House Weibull Functions Calibrating Model Parameters

As mentioned, the two in-house functions are basically the same except for returning α or β . Therefore, the script for calculating α is only given in the following.

```
Public Function weibull_afa(mn, sd)
' *****
'This function to calculate afa of Weibull
'mn = mean value of X
'sd = standard deviation of X
'inc = increment of afa
'k0 = initial value of afa
'k and c = interim variables
' *****
inc = 0.005
k0 = 0.01
```

```

k = 0
Do
k = k + 1
afa1 = inc * k + k0
beta1 = mn / gamma_function(1 + 1 / afa1)
c1 = beta1 ^ 2 * (gamma_function(1 + 2 /
afa1) - (gamma_function(1 + 1 / afa1)) ^ 2)
c1 = Abs(c1 - sd ^ 2)
afa2 = inc * (k + 1) + k0
beta2 = mn / gamma_function(1 + 1 / afa2)
c2 = beta2 ^ 2 * (gamma_function(1 + 2 /
afa2) - (gamma_function(1 + 1 / afa2)) ^ 2)
c2 = Abs(c2 - sd ^ 2)
If c2 > c1 Then
Exit Do
End If
Loop
weibull_afa = afa1
End Function

```

Earthquake Response Spectra and Design Spectra

Dimitris L. Karabalis

Synonyms

Characterization of ground motions; Earthquake ground motions; Structural response

Introduction

The design of structures capable to perform satisfactorily when subjected to earthquake ground motions requires a characterization of such motions far more detailed than the information provided by popular seismological data, e.g., the Modified Mercalli Intensity. Key role to the seismic response of a structural system plays, among others, the frequency content of the induced ground motion. All ground motions contain a broad range of frequencies and each structure is more or less sensitive to some of them. Of all the rigorous mathematical or engineering tools available to describe the frequency dependence of a seismic signal, none is simpler or more valuable, for design purposes, than the response spectrum which is a plot of the maximum response of all possible single-degree-of-freedom (SDOF) systems to a given dynamic excitation. The term “maximum response” may imply any quantity of interest, e.g., displacement, acceleration, base shear force or moment, etc., while “dynamic

Earthquake Response Spectra and Design Spectra, Fig. 1 A typical response spectrum plot

excitation” usually suggests some earthquake ground motion. Since an SDOF system is fully specified by its period (or frequency) and damping, the response spectrum is usually plotted as a function of period T (or frequency ω) for a set of damping values, as is depicted in Fig. 1.

As it is well known, the maximum response of a structure is usually dominated by its fundamental mode of vibration of, say, period T . Entering this value as the coordinate of the spectrum plot in Fig. 1, a proportional amplitude of the response of that mode, to a given earthquake ground motion, is obtained. Thus, the response spectrum can be seen as a measure of the destructive potential of a given seismic excitation. Of course, the above argument for the fundamental mode can also be extended to any of the “important” modes of vibration of a structure. Furthermore, the spectra of various recorded earthquake ground motions have been appropriately combined into design spectra, by which the ground excitation is specified in all contemporary seismic design codes. For these and other reasons, which will become obvious later, the response spectrum is a convenient and effective engineering tool which has been used universally in structural analysis and design. Apparently, Biot (1933) was the first to introduce the concept of response spectrum and Housner (1959) was the one who applied it to produce earthquake design spectra. Detailed discussions on these matters can be found in, among many others, Gupta (1990), Clough and Penzien (1993), and Chopra (1995).

Response Spectra of Earthquake Ground Motions

An SDOF elastic system of mass m , stiffness k , and damping c is shown in Fig. 2. It can be viewed as a simple single-story structure or an approximation of the first mode of a multistory building. If the SDOF system is subjected to a base motion $u_g(t)$, the equation of motion of the mass m can be written as

$$m[\ddot{u}(t) + \ddot{u}_g(t)] + c\dot{u}(t) + ku(t) = 0 \quad (1)$$

where a dot indicates differentiation with respect to time, $\ddot{u}_g(t)$ is the acceleration of the ground motion, and $u(t)$ is the relative displacement between the mass and the ground. After dividing by the mass m and rearranging terms, Eq. 1 becomes

$$\ddot{u}(t) + 2\xi\omega\dot{u}(t) + \omega^2u(t) = -\ddot{u}_g(t) \quad (2)$$

where $\omega^2 = k/m$ is the circular frequency of the SDOF and $\xi = c/2m\omega$ is its damping ratio (fraction of critical damping). Assuming the motion starts at time $t = 0$ while the structure is at rest, i.e., $u(0) = \dot{u}(0) = 0$, the solution of Eq. 2 can be expressed by the well-known Duhamel integral as

$$u(t) = \frac{-1}{\omega} \left\{ \frac{1}{\sqrt{1-\xi^2}} \int_0^t \ddot{u}_g(\tau) e^{-\xi\omega(t-\tau)} \sin[\omega_d(t-\tau)] d\tau \right\} \quad (3)$$

Earthquake Response Spectra and Design Spectra, Fig. 2 Single-degree-of-freedom system under earthquake excitation

where $\omega_d = \omega\sqrt{1-\xi^2}$ is the damped circular frequency of the SDOF system. Differentiation of Eq. 3 and simple manipulations with the trigonometric identities yield expressions for the velocity and the accelerations in a similar form, i.e.,

$$\dot{u}(t) = \frac{1}{\sqrt{1-\xi^2}} \int_0^t \ddot{u}_g(\tau) e^{-\xi\omega(t-\tau)} \sin[\omega_d(t-\tau) - \alpha] d\tau \quad (4)$$

$$\ddot{u}(t) + \ddot{u}_g(t) = \omega \left\{ \frac{1}{\sqrt{1-\xi^2}} \int_0^t \ddot{u}_g(\tau) e^{-\xi\omega(t-\tau)} \sin[\omega_d(t-\tau) - \beta] d\tau \right\} \quad (5)$$

where $\alpha = \tan^{-1} \left[\frac{\xi}{\sqrt{1-\xi^2}} \right]$ and $\beta = \tan^{-1} \left[\frac{2\xi\sqrt{1-\xi^2}}{1-2\xi^2} \right]$.

A close examination of Eqs. 3, 4, and 5 reveals that all three of them are nearly identical except for the multiplying factor in front of the right-hand side and the phase shift in the argument of the sine term in the integrand. Apparently the only difference in the values of the integrals at any time t is due to the phase shift in the sine

function. While for the velocity Eq. 4, the phase shift α is large, i.e., 90° for $\xi = 0$ and 84.3° for $\xi = 10\%$, the phase shift β in the acceleration Eq. 5 remains small, i.e., 0° for $\xi = 0$ and 11.5° for $\xi = 10\%$. For engineering purposes, the time variation of the response parameters is of no general interest. The crucial information is conveyed by their extreme values as they are related to maximum forces, deformations, etc. In addition, analyses of many strong-motion accelerograms have shown that the maximum values of the integrals in Eqs. 3 and 5 are almost the same, indicating the small influence of the phase shift on the maximum value of the integral. Similar comments can be made even for the large phase shift of the velocity Eq. 4, except for SDOF systems with large period T (small ω). In any case, in view of the random form of the ground acceleration $\ddot{u}_g(t)$, only a numerical evaluation of the integral of Eq. 3 will yield practical results. Alternatively, a solution of Eq. 2 can be obtained directly in a numerical form by a number of well-known methods, e.g., finite difference, Newmark, Runge-Kutta, etc.

It is evident from Eqs. 2 and 3 that the response $u(t)$ to a given ground motion $u_g(t)$ depends only upon the circular frequency ω and the damping ratio ξ and not upon the particular values of the stiffness k and the mass m , i.e., any

two SDOF systems with the same ratio k/m and damping ratio ξ would respond in an identical manner. Therefore, the absolute maximum response of the system can be symbolically written as

$$\max|u(t, \omega, \xi)| = SD(\omega, \xi) \quad (6)$$

where SD is a single-valued function of ω and ξ . A plot of SD versus ω or the period $T = 2\pi/\omega$ or the natural frequency $f = 1/T = \omega/2\pi$, for a fixed value of ξ , is called the *relative displacement* (or simply *the displacement*) *response spectrum* of the given ground motion $u_g(t)$. In view of Eqs. 4 and 5, similar rigorous definitions, like the one of Eq. 6, can be given for the *relative velocity* (or simply *velocity*) *response spectrum* SV and the *absolute acceleration response spectrum* SA of the ground motion $u_g(t)$. However, the form of Eqs. 3, 4, and 5 and the preceding comments about the small-to-negligible influence of the corresponding shift phases suggest the following approximate, but quite accurate for practical purposes, expressions:

$$SV = \omega SD \quad (7)$$

$$SA = \omega^2 SD \quad (8)$$

Due to their approximate nature, the SV and SA spectra defined in Eqs. 7 and 8 are frequently referred to as pseudovelocity and pseudoacceleration response spectra, respectively, and, in order to underline the difference with the rigorously defined SV and SD , the symbols PSV and PSA are also used. It should be noted that the prefix “pseudo” (from the Greek $\psi\epsilon\acute{\upsilon}\delta\omicron$, false) should not be misleading, as in this case it is used to indicate an approximation and not an incorrect concept. In this entry the symbols SV and SA will be used as defined by Eqs. 7 and 8. Figure 3 shows the Lefkada 2003 earthquake record (strong motion, T component) and the corresponding SD , SV , and SA response spectra for two values of the damping ratio, $\xi = 5\%$ and $\xi = 10\%$. Such plots illustrate the maximum response of all SDOF oscillators of practical interest to a given ground motion and, thus,

provide an almost complete description of the effects of the specific ground motion on structural response.

The motivation for the development of the response spectrum concept is rooted on the need to compute in a straightforward manner design related quantities such as maximum base shear forces, moments, etc. For example, the maximum base shear $V_{\max}$ of the SDOF system of Fig. 2 due to a specified ground motion $u_g(t)$ is

$$V_{\max} = ku_{\max} = k SD \quad (9)$$

By direct substitution from Eq. 8 and using the definition of the circular frequency ω , Eq. 9 can be also written in another useful form as

$$V_{\max} = m SA \quad (10)$$

Apparently the maximum shear force can be computed directly from the SA or SD spectra. However, it should be noted that the quantity $m SA$ is the maximum elastic shear force, while theoretically the maximum inertia force is $m \max|\ddot{u}(t) + \ddot{u}_g(t)|$. As explained earlier, the spectrum acceleration SA and the maximum absolute acceleration $\max|\ddot{u}(t) + \ddot{u}_g(t)|$ are nearly equal for almost all practical cases, except for long periods and large damping ratios. The small difference between the elastic shear force and the maximum inertia force is the damping force $c \max|\dot{u}(t)|$.

The relative velocity response spectrum, usually of secondary importance, is related to the maximum strain energy of the SDOF system, i.e., SV is equal to the velocity that gives the SDOF system kinetic energy equal to the maximum strain energy due to the earthquake ground motion. This follows from the definition of strain energy and substitution from Eq. 7, i.e.,

$$E_s = \frac{1}{2}k SD^2 = \frac{1}{2}m SV^2 \quad (11)$$

For a wide range of periods, the values of SV are quite close to those of the maximum velocity. However, a considerable difference exists between the response spectrum SV and the

Earthquake Response Spectra and Design Spectra,

Earthquake Response Spectra and Design Spectra

Spectra, Fig. 4 Tripartite response spectra plot of the 1940 El Centro (comp. NS) record (After Anagnostopoulos (1997))

maximum relative velocity $\max|\dot{u}(t)|$ for long-period structures. This can be seen on the basis of physical grounds, since for very flexible structures (large T), the elastic forces are small, the mass will exhibit very small displacements, and, thus, the relative displacements between the mass and the ground will be almost identical to the ground displacements, i.e., for $T \rightarrow \infty$, $SD \rightarrow \max|u_g(t)|$, and $\max|\dot{u}(t)| \rightarrow \max|\dot{u}_g(t)|$, but, because of the definition of SV in Eq. 7, $SV = \omega SD = \frac{2\pi}{T} SD \rightarrow 0$, since SD reaches a finite value.

From the definitions of the three response spectra provided by Eqs. 6, 7, and 8 follows the exact mathematical relationship

$$SD = \omega SV = \omega^2 SA \quad (12)$$

which implies that each of the three response spectra provides the same information as the others about a specific ground motion. Equation 12 also permits plotting, e.g., Anagnostopoulos (1997), all three response spectra by a single curve on a three-way logarithmic graph, as shown in Fig. 4 for the El Centro record and three damping values $\xi = 0, 0.05$, and 0.10 . Such plots become useful because they reveal some general trends, common to all ground

motions. A detailed discussion on these matters can be found in several sources, e.g., Chopra (1995). As explained in the following section, these common trends permit the approximation of average response spectra and the subsequent development of design spectra with high probability of accounting for the general characteristics of future seismic events.

Elastic Design Spectra

The development of earthquake design spectra is the most important application of the response spectra concept. As defined by Anagnostopoulos (1997), a design spectrum is a specification of seismic actions for design purposes, aimed at accounting for the general characteristics of expected ground motions at the site and at minimizing the dependence of earthquake resistant design on the peculiarities of specific ground motions (that will never be repeated in the future). At a first glance, an obvious characteristic of the spectral plots produced from various ground motions is their jagged shape with successive sharp peaks and valleys within small intervals of periods. In addition, each ground motion yields a unique spectral plot with

Earthquake Response Spectra and Design Spectra, Fig. 5 Newmark and Hall (1982) elastic design spectrum ($a_g = 1.0\text{ g}$)

substantial differences to the respective spectral plots of other ground motions, e.g., valleys at one of them may appear as peaks at another, while their magnitudes and periods of occurrence are usually completely unrelated. Therefore, a structural design based on any single ground motion or, equivalently, its response spectrum would assume a substantial risk.

However, spectral plots corresponding to ground motions recorded under similar conditions, e.g., similar soil profiles, comparable earthquake magnitudes, nearly equal epicentral distances, etc., exhibit, in spite of their obvious differences, some characteristic common trends. In addition, it is well known that spectral plots, in general, normalized by their respective peak ground acceleration (PGA) tend to similar values for very short or very long periods. These observations allow the development of design spectra representative of broad classes of soil, epicentral distances, etc. Thus, design ground motions are specified in the form of smooth design spectra disregarding the usual peaks and valleys produced by individual seismic records. The first design spectrum was produced by Housner (1959) on the basis of the four strongest ground motions recorded in the USA up to that time. Later, as the number of recorded ground motions

increased, a number of similar design spectra became available representing a wider range of conditions. Modern design spectral shapes are constructed as smoothed averages of response spectra of many strong ground motions, grouped according to few broad categories of soil conditions and normalized with respect to their probabilistically estimated PGA, e.g., Newmark et al. (1973), Seed et al. (1976), Mohraz (1976), and Newmark and Hall (1982).

The set of rules for the construction of design spectra proposed by Newmark and Hall (1982), the NH spectra, have played a central role in the development of modern seismic design codes. It is based on the specification of a ground motion envelope, at any given site, defined in terms of three parameters, i.e., peak ground acceleration a_g , peak ground velocity v_g , and peak ground displacement u_g . On a three-way logarithmic plot, the ground motion envelope becomes a trapezoid, as shown by the dashed line in Fig. 5.

The values of all three ground parameters can be computed by a seismic hazard analysis, but usually only a_g is computed this way, while v_g and u_g are estimated on the basis of a_g . For example, Table 1, proposed by Newmark et al. (1973), is frequently used to estimate the peak values of ground velocity and displacement.

The actual NH spectrum is an amplification of the ground motion envelope. Its ordinates A, V, and D, as shown in Fig. 5, are obtained by multiplying those of the ground motion envelope by the corresponding amplification factors proposed by Newmark and Hall (1982). These amplification factors are reproduced in Table 2 for two levels of non-exceedance probability (50 % and 84.1 %) and eight values of critical damping.

For periods up to 0.03 s, the design spectra coincide with the ground motion envelope. From this point on the design spectrum slopes until it meets the A line at a period 0.12 s. It is well known that the NH spectrum is not conservative enough for structures with long periods, e.g., periods above 1.0 s, due to several factors, such as ambiguities regarding the combination of modal responses and insufficient depiction of faraway earthquake motions. To remedy this problem, Newmark and Hall (1982) proposed a modification of the NH spectrum for the period range 1.0–6.0 s. It should be noted that although the amplification factors are constant, the shape of the ground motion envelope is not fixed, since the values of the parameters involved depend on local soil conditions or can be determined using detailed seismic hazard analyses taking into

consideration other factors, such as epicentral distance, earthquake magnitude, etc.

Seed et al. (1976) studied the effect of soil conditions based on a number of strong-motion records for various soil profiles, i.e., soft to medium clays and sands, deep cohesionless soils, and stiff soils and rock. The final recommendation of these studies, in the form of a set of smooth, normalized design spectra curves, for 5 % damping, is shown in Fig. 6.

Smooth design spectra, such as those of Newmark et al. (1973), Newmark and Hall (1982), Seed et al. (1976), and Mohraz (1976), provide the basis for most of the design codes in use today, e.g., ATC-3 (1978), UBC (1994), and EC-8 (2004). In particular, the European Standard EC-8 defines the elastic acceleration design spectrum S_e by the following set of explicit formulae:

$$\begin{aligned} 0 \leq T \leq T_B & \quad S_e = a_g S \left[1 + \frac{T}{T_B} (2.5\eta - 1) \right] \\ T_B \leq T \leq T_C & \quad S_e = 2.5a_g S \eta \\ T_C \leq T \leq T_D & \quad S_e = 2.5a_g S \eta \left(\frac{T_C}{T} \right) \\ T_D \leq T \leq 4\text{s} & \quad S_e = 2.5a_g S \eta \left(\frac{T_C T_D}{T^2} \right) \end{aligned} \quad (13)$$

where a_g is the design ground acceleration in g's, η is the damping correction factor specified in reference to the percentage of the critical damping ratio ξ as $\eta = \sqrt{10/(5 + \xi)} \geq 0.55$, S is the soil parameter, and T_B , T_C , and T_D are

corner points. The recommended values of the parameters S , T_B , T_C , and T_D , for five soil types classified as A, B, C, D, and E are given in Table 3 for the Type 1 and Type 2 spectra. Type 2 spectrum is recommended for sites where the earthquakes that contribute most to the seismic hazard defined for the site for the purpose of probabilistic hazard assessment have a surface-wave magnitude, M_s , not greater than 5.5. The five soil types vary from rock soil profile A with a shear wave velocity $v_s > 800$ m/s to soft soil profile E with $v_s < 180$ m/s. A plot of the EC-8 elastic response spectra S_e , for $\eta = 1$, as shown in Fig. 7.

The design spectra discussed above do not take into account the influence of key seismological factors, such as the epicentral distance or the magnitude of the earthquake, on the frequency content of the motion. This is due to the fact that their shape is fixed, while the actual ordinates of the spectra are obtained by a multiplication with a

scaling factor (the design ground acceleration, obtained by site seismic hazard analysis). As a result, design spectra defined through these procedures fail to provide a uniform non-exceedance probability for all spectral regions. As an example, McGuire (1978) has pointed out that such design spectra undervalue spectral velocities, except for high frequencies, in regions affected by distant earthquakes. A partial cure to this problem has been proposed in ATC-3 where a second variable related to the peak ground velocity is introduced, in addition to the peak ground acceleration. This procedure permits the usage of a variable spectral shape but it requires the availability of two seismic hazard maps, one for the peak ground acceleration and another for the peak ground velocity. However, uniform hazard spectra, providing uniform probability of non-exceedance, are possible nowadays via regression analyses on response spectra of large

Earthquake Response Spectra and Design Spectra, Fig. 7 EC-8 elastic response spectra and design spectra: (a) Type 1 and (b) Type 2 ($\eta = 1$, $q = 4$)

numbers of strong ground motion records available on almost every region of the world, e.g., McGuire (1977) and Joyner and Boore (1982).

Inelastic Response and Design Spectra

In a manner similar to the previously described elastic response spectrum, one can define the inelastic response spectrum as a plot of the maximum response of all nonlinear single-degree-of-freedom (SDOF) systems to a given dynamic excitation. Of course, in this case the type of the nonlinearity of the oscillators of interest should be specified a priori. Inelastic response spectra, based on some nonlinear force–displacement relationship of an SDOF oscillator, are computed similarly to the elastic response spectra. Thus, in Eq. 1 the term $ku(t)$, the elastic resistance force, is substituted by the displacement-depended force $F[u(t)]$ and the equation of motion (2) is now written as

$$\ddot{u}(t) + 2\zeta\omega\dot{u}(t) + \frac{F[u(t)]}{m} = -\ddot{u}_g(t) \quad (14)$$

The simplest and most common case refers to an oscillator whose nonlinear resistance is assumed to be elastoplastic with an initial stiffness k and yield displacement u_y corresponding to a

maximum force F_y , as shown in Fig. 8. Provided the yield quantities F_y and u_y are known properties of the SDOF under investigation, the search for the quantity of interest $u_{\max}$, the maximum displacement, is facilitated by the introduction of the nondimensional ductility ratio μ defined by $u_{\max} = \mu u_y$. Thus, the ductility ratio μ , i.e., the inelastic deformation demand imposed by a ground motion $\ddot{u}_g(t)$, becomes the primary quantity of interest even for design purposes, replacing the maximum force or stress used in elastic design.

The definitions of the inelastic displacement ($SD = u_{\max}$), (pseudo)velocity (SV) and (pseudo) acceleration (SA) response spectra, and their inter-relationships, follow those of the elastic case. The SA is obtained from the formula providing the maximum elastic force, i.e., $F_y = mSA$, and, as in the elastic case, is a close approximation of the maximum absolute acceleration spectrum. In view of the relationships

$$F_y = ku_y = m\omega^2 u_y, \quad (15)$$

the above definition of SA can be written in alternative forms as

$$SA = \omega^2 u_y = \omega^2 \frac{u_{\max}}{\mu} = \omega^2 \frac{SD}{\mu} \quad (16)$$

Earthquake Response Spectra and Design Spectra, Fig. 8 Idealized elastoplastic system

Earthquake Response Spectra and Design Spectra, Fig. 9 Inelastic response spectra (SA) of the Lefkada (Greece) 2003 earthquake (14/08/2003 5:18:48 (GMT), OTE building, Lefkada, T horizontal component, $PGA = 0.42$ g)

The (pseudo)velocity spectrum can be defined in exactly the same manner as for the elastic case, i.e., $SV = SA/\omega$, in which case Eq. 16 can be expanded to include all three response spectra as

$$SA = \omega SV = \omega^2 \frac{SD}{\mu} \quad (17)$$

Apparently, Eq. 17 expresses the same relation between the three response spectra as its elastic

counterpart Eq. 12, except for the entrance of the ductility ratio μ between SD and the other two response spectra SA and SV.

For specified values of viscous damping ξ and ductility ratio μ , the computation of inelastic response spectra, for any value of ω or T , is a trial-and-error process which aims at calculating the yield force F_y which corresponds to the specified ductility ratio μ . In Fig. 9 the inelastic

response spectra (SA) of the Lefkada 2003 strong-motion record is shown for several values of the ductility factor μ . Of course, the case $\mu = 1$ coincides, as it was expected, with the linear response spectra shown in Fig. 3.

Regarding the development of inelastic design spectra, Newmark and Hall (1982) proposed a set of simple rules to obtain them from the corresponding elastic design spectra. They are based on observations related to the tendencies of the inelastic response spectra, as compared to the corresponding elastic ones, when they are plotted in a tripartite logarithmic graph. Thus, for the various characteristic regions of the elastic design spectra, proposed by Newmark and Hall (1982), the inelastic design spectra are obtained from the corresponding elastic ones by a simple multiplication with a factor which is a function of the ductility ratio μ . For more details the reader is directed to the original publication by Newmark and Hall (1982) and a detailed discussion by Chopra (1995). Following the Newmark and Hall proposals, inelastic design spectra have been developed into the most popular way of estimating the inelastic behavior of structures via standard elastic modal analyses. Modern codes have, in general, adopted this approach by simplifying the Newmark and Hall rules for inelastic design spectra and, at the same time, introducing the so-called capacity design provisions for the purpose of allowing control over the yield patterns of a structure and avoiding excessive local ductility demands, e.g., Anagnostopoulos et al. (1978). Thus, the response modification factor or behavior factor is used to account for the inelastic building behavior. Almost all of the contemporary design codes, e.g., ATC-3 (1978), NEHRP (1994), UBC (1994), and EC-8 (2004), employ a constant response modification factor, dependent upon the building material and type of structure, by which the elastic design spectrum is divided in order to obtain the corresponding inelastic one. In particular, the EC-8 inelastic acceleration design spectra S_d , used in conjunction with standard modal analysis, are specified (see for

comparison the corresponding elastic spectra of Eq. 13) as

$$\begin{aligned}
 0 \leq T \leq T_B & \quad S_d = a_g S \left[\frac{2}{3} + \frac{T}{T_B} \left(\frac{2.5}{q} - \frac{2}{3} \right) \right] \\
 T_B \leq T \leq T_C & \quad S_d = 2.5 a_g \frac{S}{q} \\
 T_C \leq T \leq T_D & \quad S_d = 2.5 a_g \frac{S}{q} \left(\frac{T_C}{T} \right) \\
 T_D \leq T & \quad S_d = 2.5 a_g \frac{S}{q} \left(\frac{T_C T_D}{T^2} \right) \\
 \text{For all periods} & \quad S_d \geq 0.2 a_g
 \end{aligned} \tag{18}$$

The symbols used in Eq. 18 are the same as those used in the corresponding elastic spectra of Eq. 13, while the values of S , T_B , T_C , and T_D remain the same to those listed in Table 3. The behavior factor q , depending on the type of the structure and the building material used, varies from 1.5 for unreinforced masonry structures to 6.0 for the most ductile steel structures. The viscous damping factor η of Eq. 13 is removed since the behavior factor q accounts for the influence of the viscous damping as well. A plot of the EC-8 design spectra S_d , for $q = 4$, is shown in Fig. 7.

Design spectra based on specific values of the ductility factor μ are introduced in the New Zealand seismic code (1992) with certain restrictions that rule out the possibility the ductility demand to exceed the provided capacity.

Summary

The response spectrum concept is defined, and its key role in the characterization of seismic motions, for engineering purposes, is described. The development and the importance of seismic design spectra, both elastic and inelastic, are analyzed and on this basis the main features of several contemporary design codes are outlined. A number of numerical examples, related to response and design spectra, are shown and discussed.

Introduction

Seismic-resistant design of structures aims primarily at preventing loss of life and global collapse.

The most common approach used worldwide is the design of structures with a large ductility capacity, thus, to be able to withstand inelastic deformation during strong ground shaking with a small collapse probability. However, the anticipated damage to structural and nonstructural components and contents that is caused by large deformations can have serious impact on post-earthquake functionality and often require, if not demolition, certainly costly and disruptive repairs. On the other hand, the design of stiffer and stronger, non-ductile structures could minimize deformations and therefore damages. However, issues such as increased material quantities, structural accelerations, and damage to acceleration-sensitive nonstructural components and building contents have to be carefully assessed in such design approaches. An alternative approach toward the limitation of structural damages under strong ground shaking is the modification of structural characteristics, in a way that the capacity is increased and/or demand is reduced. Modern technologies that can be implemented for these purposes are damping devices, base isolation schemes, or a combination of both.

Earthquake frequency occurrence or return period is directly incorporated into seismic actions and contemporary seismic norms, since in general, seismic-resistant structures must have (i) the capacity to resist frequent (with return period 50–100 years), minor earthquakes without damage, (ii) the capacity to resist with limited structural and nonstructural damage infrequent (with return period approximately 500 years) moderate earthquakes, and (iii) the capacity to resist without collapse and life safety endangerment very strong and rare earthquakes (with return period approximately 2,500 years). For more critical infrastructures, even higher seismic demand levels are imposed which is interpreted in terms of a very large return period, e.g., 10,000 years for maximum design earthquake (MDE) motions for major dams in New Zealand.

The majority of seismic norms belong to the category of prescriptive design codes (or limit state design procedures), as their aim is to ensure that the structural design satisfies a number of

checks in order to be considered safe and reliable against collapse. A typical limit state-based design can be viewed as a one-limit state, ultimate strength, or a two-limit state approach, serviceability and ultimate strength. Most of the prescriptive design codes are based on the assumption that structures are capable of dissipating energy through inelastic deformations. It is recommended to design ductile structures provided that ductility remains within the prescribed limits. Seismic loads can significantly be reduced (via the so-called behavior factor) if the structure is designed to be dissipative.

Furthermore, serviceability is usually checked to ensure that the structure will not deflect or vibrate excessively during its service life. Structural assessment is typically performed considering ultimate strength limit state under the design earthquake (typically with return period of 475 years and probability of exceedance 10 % in 50 years) and damage limitation under an occasional earthquake for the serviceability limit state (typically with return period of 72 years and probability of exceedance 50 % in 50 years). These two hazard levels are the most generally used worldwide. In certain norms (e.g., US guidelines (FEMA-750 2009), it is also specified that structures should be capable to withstand (i.e., to avoid global collapse) the so-called maximum considered earthquake (typically, having return period equal to 2,475 years and probability of exceedance 2 % in 50 years).

The most common approach for the definition of the seismic input is the use of a design code response spectrum which is created for a certain return period of earthquake hazard. This is a general approach, which is easy to implement for conventional buildings. Moreover, if higher precision is required, the use of spectra derived from suitable earthquake records is more appropriate. Note that significant dispersion on the structural response due to the use of different records even scaled to the same earthquake intensity can be observed, since ground motions with equal peak ground acceleration (PGA) but different frequency content can have very different demands upon a structure.

Response spectrum method (RSM) has become the basic computational tool in earthquake-resistant design of structures, mainly because of its simplicity as it basically uses two parameters: spectral period and damping ratio. The principal weakness of the RSM is that it does not include the duration and other aspects related to frequency content of a strong motion, thus, especially for higher seismic intensities, and it is incapable to fully cover all aspects of dynamic nonlinear response. To overcome this deficiency, dynamic analysis methods (linear and preferably nonlinear) can be used utilizing historic, simulated, or synthetic acceleration time histories. Toward this goal, recent guidelines (e.g., FEMA-445 2006) suggest the use of more accurate dynamic analysis procedures for structural design and assessment. Input motions should be representative of regional seismicity and must be compatible with each earthquake hazard level; thus, various methodologies have been proposed to select and scale accelerograms (e.g., Katsanos et al. 2010).

The modern conceptual approach for structural design and assessment is the so-called performance-based design (PBD) approach, which is based on the principle that a structure should meet certain performance objectives for multiple seismic hazard levels. Regarding seismic hazard, it ranges from frequent (i.e., having a small return period) earthquakes of low intensity to more catastrophic and rare events that have large period of occurrence. This framework has been introduced in order to increase structural safety against natural hazards. According to PBD, the structures should be able to resist earthquakes in a quantifiable manner and to present levels of possible damage in a prescribed preferable manner (e.g., avoiding soft-storey collapse). In any case, the adoption of a proper stochastic model (usually the Poisson distribution) for the occurrence of earthquake events has to be used within an elaborate seismic hazard analysis. In addition, the construction of a seismic hazard curve is needed to associate a particular ground motion parameter (e.g., peak ground acceleration, spectral acceleration, etc.) with an annual frequency of exceedance or

the probability of exceedance in a given time period (typically for a 50-year period).

Seismic Hazard Analysis

Seismicity at a site is typically defined as a quantitative estimation of ground shaking, which may be represented most commonly by peak ground acceleration (PGA) (as well as velocity (PGV) and displacement (PGD)), or response spectrum ordinates (mostly accelerations). It has to be stressed that in this work, the emphasis on seismic hazard in terms of return period is given on ground shaking. Nonetheless, similar analysis related to kinematic distress and various soil failure types (fault rupture (Angell et al. 2003), liquefaction (Kramer and Mayfield 2007), landslides (Saygili 2008), etc.) due to earthquakes needs to be considered in certain occasions, especially for lifelines that are frequently exposed to such perils. The severity of these hazards (i.e., probability of exceedance) used in performance evaluation should be compatible with that used in the specification of ground shaking hazard levels (FEMA-350 2000).

In any case, the main aim in seismic hazard analysis is the estimation of the most crucial parameters related to earthquake hazard that is expected to occur at a given site during a predefined time interval, the so-called return or recurrence period. Seismic hazard analysis requires the knowledge of certain important data for the wider neighborhood of the examined site, such as geologic evidence of earthquake sources, fault activity, historical seismicity data, etc. Past earthquake data provide valuable information for predicting the magnitude and occurrence frequency of future earthquakes and, thus, are most valuable in seismic hazard analysis. Recently a substantial effort has been devoted to the development of a global earthquake model (GEM) and open-source software for seismic hazard and risk assessment (for more details, visit <http://www.globalquakemodel.org/openquake/about/engine/>).

At this point, it is necessary to clarify the difference between the two commonly used terms “hazard” and “risk.” These terms are

often used interchangeably, which is misleading. For instance, one of the main hazards associated with earthquakes is ground shaking irrespective of its consequences. On the other hand, seismic risk is associated with structural damage and collapse and, possibly, loss of life. Hence, in general, seismic hazard analysis describes the potential for dangerous, earthquake-related natural phenomena, mainly for ground shaking but also for fault rupture, liquefaction, etc. Utilizing this information, seismic risk analysis assesses if the probability of occurrence of losses (human, social, financial) associated with such seismic hazards will exceed a target value in a specified period of time.

Seismic hazard analysis can be performed using two approaches, namely, deterministic seismic hazard analysis (DSHA) and probabilistic seismic hazard analysis (PSHA). Both use similar information to determine the “design earthquake,” while other hazard levels can also be established. Basic elements of deterministic analysis are also included in the probabilistic approach. The main difference is that the probabilistic approach takes into account the uncertainties and the likelihood of an actual earthquake exceeding the design ground motion. Examples of the outcome of the two approaches are as follows (FEMA-451B 2003):

- Deterministic seismic hazard analysis: “The earthquake hazard for the site is a peak ground acceleration of 0.24 g resulting from an earthquake of magnitude 6.0 from a specific fault at a distance of 50 km from the examined site.”
- Probabilistic seismic hazard analysis: “The earthquake hazard for the examined site is a peak ground acceleration (PGA) of 0.50 g with a 2 % probability of being exceeded in a 50-year period.”

Comparisons among PSHA and DSHA have been made by many researchers in the field (e.g., Krinitzsky 1995; Bommer et al. 2000). Overall, DSHA approach provides a clear and simple method for computing seismic hazard, and its assumptions can be easily discerned. Using DSHA, it is relatively easy to derive

comprehensible hazard scenarios. Nonetheless, it does not have any mechanism to account for uncertainties, while findings based on DSHA can easily be upset by the occurrence of new earthquakes. On the other hand, PSHA is capable of integrating a wide range of data and uncertainties into a flexible framework. Unfortunately, its highly integrated framework can obscure those elements which influence more the results, and its highly quantitative nature can lead to false impressions of high accuracy which is not always true.

In general, none of the two methods is superior to the other for all cases, although PSHA is more frequently used. DSHA is still used for some significant structures, such as nuclear power plants, large dams and bridges, hazardous waste containment facilities, etc. Occasionally, the best solution is to use DSHA and PSHA in a complimentary manner, i.e., DSHA may be used as a “cap” for probabilistic analyses to define the “maximum expected earthquake” and PSHA for the more frequent operational basis earthquake. Nevertheless, the most important is to realize that both methods are simply tools to assist in earthquake mitigation. In any case, the results of a seismic hazard analysis, performed either deterministically or probabilistically, are needed by engineers to perform seismic analysis and design. In the sequence, the basic ingredients of the two methodologies are briefly described, with emphasis on earthquake return period and its incorporation into both approaches.

Deterministic Seismic Hazard Analysis

DSHA is based on the magnitude and distance, which yields the largest ground motion amplitude at the site of interest. Under this perspective, the four primary steps in DSHA (see Fig. 1) are as follows (Kramer 1996):

1. Identification and characterization of all sources.
2. Selection of “controlling earthquake”.
3. Selection of source-site distance parameter.
4. Definition of hazard using controlling earthquake.

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 1 Basic steps in DSHA (Modified from FEMA-451B (2003))

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 2 Example of DSHA (Adopted from FEMA-451B (2003))

The first step is to identify all possible sources of ground motion, while some may be rather easy to identify (e.g., a known active fault), others may be more difficult to describe. Subsequently, the controlling earthquake needs to be defined, and this involves engineering judgment. For instance, if one wants to design for the largest earthquake that could ever occur at the site (using perhaps an estimate of seismic moment) or the largest motion that has occurred within a time period (e.g., the past 500 years). Note that as aforementioned, there is no inclusion of aspects related to probability of occurrence related to regional seismicity.

Selection of source-site distance parameter is also important for the DSHA process. In DSHA, it is common to use the closest distance from

a source to the examined site. As the known earthquakes will have occurred at a distance that is not likely to be the same as the distance to the site, certain correction needs to be made to take into account geometric spreading of seismic waves and seismic energy absorption. This is done utilizing attenuation models that have been established for each region, as it is very important to use attenuation relationships that characterize local geotectonics.

Figure 2 presents a very simple example of DSHA, in which three sources were considered, while in each case the closest distance to the site was used. Note the different magnitudes for the different sources, which are consistent with the selected “maximum earthquake”. The peak ground acceleration (PGA) at the site was

obtained from an appropriate attenuation relationship. The motion with the greatest resulting PGA is chosen as the controlling earthquake. Note that this is not sufficient to establish seismic risk, since the effect of the motion on the examined structure is not addressed. It is worth mentioning that under certain circumstances, the more distant earthquake, though having a lower effective PGA, could produce waves at a frequency that could be more damaging for a specific structure.

Identification and characterization of all sources can be performed in DSHA utilizing slip rate approach, in which if average displacement over the slip surface, D , relieves stress/strain buildup by movement of the lithospheric plates over a certain time period, t . Therefore, $D = S \cdot t$, where S is the slip rate at the examined fault. Subsequently, the seismic moment is given by

$$M_o = \mu \cdot A \cdot S \cdot t = \mu \cdot A \cdot D \quad (1)$$

where μ is the rigidity or shear modulus of the bedrock, usually taken equal to $\approx 3 \times 10^{11}$ dyne/cm², and ζ is the rupture area on the fault plane where the slip occurs during the earthquake. In addition, the “moment rate” can be defined as $M_o/t = \mu \cdot A \cdot S$. The seismic moment is transformed to earthquake magnitude or energy according to simple logarithmic expressions.

The resulting hazard statement of DSHA is basically a “scenario” earthquake for seismic design (i.e., design earthquake). The rather conservative way that DSHA is commonly used produces a worst-case scenario. DSHA provides no indication of how likely design earthquake is to occur during lifetime of a structure. Design earthquakes may occur every 200 years in some places and every 10,000 years in others. Furthermore, DSHA require subjective opinions of the seismologist on input parameters, while variability of effects is not rationally accounted for.

Probabilistic Seismic Hazard Analysis

Probabilistic seismic hazard analysis (PSHA) was introduced by Cornell (1968). In contrast to DSHA, it assumes many scenarios, in which it

considers all magnitudes, all distances, and all effects. Furthermore, PSHA considers uncertainty in location, size, rate of earthquake occurrence, predictive relationship, etc., and combines them to compute probabilities of different levels of ground shaking. In particular, PSHA integrates site’s total seismicity for a given time period and provides strong-motion parameters within predefined confidence levels, in the form of hazard curves, uniform response spectra, etc., for various return periods. In general, as shown in Fig. 3, PSHA consists of four primary steps (Kramer 1996):

1. Identification and characterization of all source zones (areas or faults) based on historical seismicity, tectonics, and geology.
2. Characterization of seismicity of each source, i.e., to determine an upper magnitude limit and develop a magnitude-recurrence relationship for each source zone.
3. Determination of a predictive relationship for seismic parameter motions (such as PGA) from each source.
4. Perform probabilistic calculations to compute the probability distribution of ground motion at the site and select the design value at the appropriate probability level.

Ground motion parameters that can be derived from a PSHA include: PGA and spectral acceleration (S_a) hazard curves, uniform response spectra (URS), de-aggregation of hazards by magnitude and distance, and parameters for assisting in time-history selection for dynamic analysis. A seismic hazard curve is constructed by plotting the rate of exceedance of the seismic parameter for different seismic intensity levels. In order to assess that a certain engineering demand parameter (e.g., drift) will be exceeded in a building located at a certain site, it is essential to evaluate the accuracy in terms of the mean annual frequencies (MAF) of exceedance given in a form of hazard curve, as in Fig. 4 in terms of PGA values (or alternatively using spectral acceleration values). Similar curves can be constructed for a kinematic type of seismic hazard. For example, utilizing the so-called probabilistic fault

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 3 Basic steps in PSHA (Adopted from FEMA-451B (2003))

Steps in Probabilistic Seismic Hazard Analysis

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 4 Typical hazard curve of PGA values in terms of annual frequency rate

displacement hazard analysis (PFDHA), one can derive fault displacement hazard curves that represent annual frequencies (and corresponding return periods) of certain fault slippage level (Angell et al. 2003).

Frequently, fractile curves (e.g., 15th, 50th, 85th percentiles) of hazard curves are also plotted together with the mean curve to illustrate data scattering. Note that differences between mean and median curves can be observed. Equivalently, seismic parameters can be interpreted as

a function of return periods, as shown in Fig. 5. Tools for producing hazard curves as those shown in Figs. 4 and 5 as well as response spectra, etc., can be found at US Geological Society (USGS) site: <http://earthquake.usgs.gov/hazards/>.

Earthquake Occurrence Frequency

According to PSHA, a given source can produce different earthquakes: low-magnitude earthquakes occur often and cause fewer damages,

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 5 Typical hazard curve of PGA in terms of return periods

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 6 Schematic representation of magnitude and mean annual recurrence in exponential and log-linear forms

while large magnitude and more severe events occur rarely. The latter have longer return periods and lower probability of exceedance, yet they are more catastrophic; thus, they are referred as low probability – high consequence events. In a probabilistic analysis, the recurrence relationship (e.g., frequency of earthquakes above a certain magnitude) needs to be included as it is the major uncertainty of the process. All major uncertainties are included in PSHA, and the result is a seismic hazard curve that relates the design motion parameter to a probability of exceedance. Hence, for the design of a bridge for a ground motion with a 2 % probability of being exceeded in a 50-year period (which is transformed to annual probability), the ground motion parameter (e.g., PGA) is obtained from the seismic hazard curve (such as the one in Fig. 4).

Typically, the seismicity is interpreted using a specified relationship between magnitude and likelihood of occurrence and is called “recurrence relationship,” which indicates the average rate at which an earthquake of a particular magnitude, M , will be exceeded as shown in Fig. 6. Such relationships are determined from regression analysis of historical earthquake data. The most popular is Gutenberg-Richter model which is a rather simple mathematical formulation that is reliable for intermediate scale events but may be insufficient for small or for large earthquakes; thus, more advanced models have been proposed (Kramer 1996).

According to the Gutenberg-Richter recurrence, law earthquake magnitudes are exponentially distributed and the mean rate of occurrence (i.e., the number of earthquake events/year equal

to or greater than magnitude M), λ_M , is defined in log-linear or exponential form (see plots in Fig. 6) as follows:

$$\log \lambda_M = a - b \cdot M \Rightarrow \lambda_M = 10^{(a-b \cdot M)} = e^{(\alpha - \beta \cdot M)} \quad (2)$$

and following the above formulation, the event return period is directly given by

$$T_R = \frac{1}{\lambda_M} = \frac{10^{b \cdot M}}{10^a} \quad (3)$$

where a and b (while $\alpha = 2.303 \cdot a$ and $\beta = 2.303 \cdot b$) are regional parameters determined from tectonic and geological data, rate of seismicity, etc.; typically, b is close to unity ($b = 1.0 \pm 0.5$) and represents the relative likelihood of large and small events.

Temporal Earthquake Uncertainty

The temporal uncertainty of earthquakes is included in PSHA by considering the distribution of their occurrence in time, which can be modeled by random models, such as Bernoulli, Poisson, and Markov processes. In this manner, it is possible to calculate the probability of the number of occurrences over a certain time interval. The occurrence of an earthquake for a certain time interval is usually modeled as a Poisson process that describes the number of occurrences of an event (not only earthquakes but floods and other natural disasters as well) during a specified time interval and provides also the return period of such event. The main assumptions of Poisson model are as follows (Kramer 1996):

1. The number of occurrences over a given time interval are independent of the number of earthquakes that occur in any other time interval (i.e., the system has no memory from past seismic history, while there are other time-dependent models that keep track of occurred events).
2. The probability of occurrence in a very short time interval is proportional to the length of the interval.

3. The probability of more than one occurrence in a very short time period is negligible.

According to the popular Poisson model, the temporal distribution of earthquake recurrence for a certain intensity level (magnitude, PGA, etc.) is given by

$$P[N = n] = \frac{\mu^n e^{-\mu}}{n!} \text{ or } P[N = n] = \frac{(\lambda \cdot t)^n e^{-\lambda \cdot t}}{n!} \quad (4)$$

where n is the number of occurrences and $\mu = \lambda \cdot t$ is the average number of occurrences in the time interval of interest, t , and λ is the annual rate, which is directly related to the return period of such event as shown in Eq. 3. Hence, the probability that an earthquake having a specific ground motion parameter, such as magnitude, higher than a certain level, will occur at least once in t years is given by

$$\begin{aligned} P[N \geq 1] &= P[N = 1] + \dots + P[N = \infty] \\ &= 1 - P[N = 0] = 1 - e^{-\lambda \cdot t} \\ &= 1 - e^{-t/T_R} \end{aligned} \quad (5)$$

The above expression can be easily combined with a recurrence law (as the one in Eq. 2) to predict the probability of at least one exceedance of a specific magnitude M , λ_M , in a period of t years as follows:

$$P[N \geq 1] = 1 - e^{-\lambda_M \cdot t} \quad (6)$$

An example of using Eq. 5 is to calculate the probability that an event that occurs on average every 1,000 year will occur at least once in a $t = 100$ -year period. Thus, $\lambda = 1/1,000 = 0.001 \Rightarrow P = 1 - \exp[-(0.001)(100)] = 0.0952 = 9.52\%$, while the probability that one such event will occur at least once in a 1,000 year period is $P = 1 - \exp[-(0.001)(1,000)] = 0.632 = 63.2\%$. Obviously, this probability value (63.2 %) is the same for all hazard level return periods when the examined time interval is equal to the return period: $t = T_R$.

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 7 Example of relationship between return period, time interval of interest, and probability of exceedance PSHA (Adopted from FEMA-451B (2003))

Apart from the probability of exceedance, the level of ground shaking that has a certain probability of exceedance in a given period can be determined via Eq. 5 and a hazard curve as it will be shown in the next section. Furthermore, solving Eq. 5 for annual rate (events per year), λ , gives

$$P[N \geq 1] = 1 - e^{-\lambda t} \Rightarrow \lambda = -\frac{\ln(1 - P)}{t} \quad (7)$$

and the corresponding return period, T_R , is given by

$$T_R = \frac{1}{\lambda} = -\frac{t}{\ln(1 - P)} \left(\approx \frac{t}{P} \right) \quad (8)$$

For example, the annual rate of exceedance for an event with a 10 % probability of exceedance in 50 year, or in short 10/50 hazard level, is given by $\lambda = -(\ln(1-0.1)/50) = 0.0021/\text{year}$, while the corresponding return period is $T_R = 1/\lambda = 475$ years. Similarly, for 2 % in 50 year, $\lambda = 0.000404/\text{year}$ and $T_R = 2,475$ years.

As indicated in the last part of Eq. 8, for low probabilities (or long return periods), the return period is approximately equal to t/P . For example, for a period of 100 years and return period of 2,500 years, the 100-year probability is roughly equal to $P = t/T_R = 100/2,500 = 4$ % approximately equal to 3.96 % which is the exact outcome of Eq. 8. Nonetheless, this approximation is

not valid for higher probabilities. For instance, the actual return period of 50 % probability of exceedance in 50 years is 72 years, not 100 years as suggested by the approximate formula. Note also that since λ depends on P and t values, there are many pairs of P and t that result to the same return period.

Figure 7 depicts the relationship between return period, time interval of interest, and the related probability of exceedance. For instance, a 2 % probability for an event of being exceeded in 50 years has a return period of 2,475 years, while a 10 % probability of exceedance in 50 years has approximately a 475-year return period. Such curves are very useful for assessing multiple hazard levels in performance-based design approaches. For structural design, a 50-year base line is generally used, since this is estimated as the service life of a typical building. For critical infrastructures, such as dams, a longer return period is more appropriate as the required functioning life is much longer and failure consequences more severe.

Probability of exceedance must be associated to a time interval of interest and to be connected to a certain return period, which is simply described by its value. For example, an earthquake with a 2 % probability of being exceeded in 100 years has a return period of $T_R = -100/\ln(1-0.02) = 4,950$ years. Note that since the precision of knowledge of this natural phenomenon is not perfect; thus, the return periods can be

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 8 Example of seismic hazard curves derived from PSHA

rounded, e.g., the computation of a return period of 474 years for the 10 %/50 year hazard level can be rounded to 475 years and even more for higher hazard levels (i.e., $T_R = 2,475$ to be set 2,500 for 2/50 level). In addition, utilizing Poisson model, one can compare different probabilities for different time intervals. For instance, utilizing Eq. 7 it is straightforward to compare a 2 %/50-year event with a 10 %/250-year event. For 2 %/50 years, $T_R = 50/(-\ln(1-0.02)) = 2,475$ years, while for 10 %/250 years, $T_R = 250/(-\ln(1-0.10)) = 2,372$ years. Hence, these events (expressed with different probabilities) are not exactly equal from a statistical point of view, yet they can be considered equivalent from an engineering perspective.

Seismic Hazard Curves

As shown in Fig. 8, a seismic hazard curve represents the mean annual rate of exceedance of a particular ground motion parameter (peak or spectral accelerations, etc.). In other words, the vertical axis provides the (desired) level of probability, while the horizontal axis depicts a ground motion parameter, such as peak ground acceleration. A seismic hazard curve is the ultimate result of a PSHA after combining all uncertainties and performing necessary probability computations. Contribution of independent sources can be interpreted in different seismic hazard curves (to illustrate which sources are more important) together with the total seismic

hazard curve, as presented with the continuous line which is the outcome of all dashed lines in Fig. 8.

The potential usages of seismic hazard curves are illustrated in Fig. 9. In the left plot (Fig. 9a), the aim is to calculate the probability of exceeding $a_{\max} = 0.35$ g in a 50-year period. As it is shown in the graph, $\lambda = 0.001$; thus, $P = 1 - e^{-\lambda t} = 1 - \exp[-(0.001)(50)] = 0.049 = 4.9$ %. Similarly, in a 500-year period, the probability of exceedance is $P = 1 - \exp[-(0.001)(500)] = 0.393 = 39.3$ %. In a reverse manner, as depicted in the right plot (Fig. 9b), to calculate what peak acceleration has a 10 % probability of being exceeded in a 50 year period, i.e., 10 % in 50 year, then $\lambda = 0.0021$, or $T_R = 475$ years and as it can be derived from the seismic hazard curve, the $a_{\max}$ value corresponding to $\lambda = 0.0021$ is equal to 0.24 g.

Uniform Response Spectra

Uniform response spectra (UHS) represent spectral ordinates (most frequently accelerations) and are widely used in seismic norms in simplified forms, as the one shown with the continuous line in Fig. 10. Developed from PSHA, UHS is a cumulative graph (constructed from many response spectra derived from records as the one with the dashed line shown in Fig. 10 which is the outcome of a pulse-like accelerogram) that provides, for each spectral period, the spectral amplitude that has a specified probability of exceedance or return period. Therefore, the probability of exceeding a UHS is constant (or uniform) as a function of return period. In other words, a UHS represents a composite of all earthquakes that contribute to site-specific hazard curve; thus, response spectra have the same statistical characteristics as the hazard curve used for their generation. Note that a UHS may not resemble the response spectrum from any specific earthquake magnitude and distance of the site. In addition, it may be too conservative for dynamic analysis and may not be appropriate for artificial ground motion generation.

If a series of seismic hazard curves is developed for a range of different parameters (e.g., PGA or spectral acceleration for 0.2 s or 1 s)

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 9 Examples of using seismic hazard curves for calculating: (a) exceedance probabilities, and (b) ground motion parameters

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 10 Example of typical response spectrum pattern in seismic norms (continuous line) and a response spectrum derived from a pulse-like accelerogram (dashed line)

and values are extracted for a certain confidence level (e.g., a 10 % in 50 year probability of exceedance), then a response spectrum may be created by plotting the parameter magnitudes in terms of spectral period, T . The plot at the lower left in Fig. 11a shows the first point on such a spectrum, in this case: the PGA with a 10 % probability of being exceeded. Similarly, in Fig. 11b, the point representing the 0.2 s (5 % damped) spectral ordinate with the same (10 %) probability of being exceeded in 50 years is plotted. In this manner, the whole response spectrum is constructed as shown in Fig. 10.

If the process is repeated for every return period of interest, then design spectra for different hazard levels can be constructed, as shown in Fig. 12. If the aforementioned procedure is continued for many earthquake records, the result is a complete UHS that can be used in a simplified form in seismic norms (see Fig. 10). Such multiple spectra can be used in response spectrum analysis of a structure within a performance-based design

framework. Similar plots can be produced for spectral displacements or velocities.

Note that the information derived from PSHA may be used to assist in the development (selection and scaling) of suitable ground motion time histories (Katsanos et al. 2010). For this purpose, the ground motion amplitudes is scaled in a way that the spectrum of the scaled ground motion closely matches a target UHS. Nonetheless, this can lead to inaccurate results, since the UHS is a composite of hundreds if not thousands of earthquakes, any two of which are very unlikely to occur simultaneously. Typically, the short period part of the UHS is representative of moderate nearby earthquakes, while the long-period part reflects the hazard from larger, more distant events. Figure 13 illustrates more clearly this point. Although it is possible to generate a realistic earthquake ground motion that matches small or large earthquakes, a generated earthquake that matches the whole UHS would be unrealistic and most probably too demanding for the structure.

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 11 Example of using seismic hazard curves for generating a design response spectrum

to determine: (a) PGA and (b) S_a for 0.2 s (Adopted from FEMA-451B (2003))

Proper hazard maps can be used to construct uniform response spectra that can be used for seismic design of structures. For instance, in the United States (US), seismic provisions are based on probabilistic maps developed by USGS after performing elaborate probabilistic seismic hazard analyses of the entire USA (Petersen et al. 2008). Using these maps, which provide spectral values for different spectral periods (e.g., for 0.2 s in the S_a 2/50 map of Fig. 14), it is possible to develop damped response spectra (for a specific structural damping ratio, typically

5 %) for a variety of exceedance probabilities (e.g., 2/50, 10/50, etc.) as illustrated in Fig. 14.

In many countries worldwide, there are hazard maps for different PGA or spectral ordinates and for various mean return periods (e.g., details for the USA are given at the theme issue of Earthquake Spectra (2000)). Such European hazard maps have been recently developed (both for PGA and spectral accelerations for various return periods: 101, 475, 975, 2,475 years) in the framework of SHARE project (www.share-eu.org). Figure 15 depicts the UHS for 10 % probability

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 12 Example of design spectra for different hazard levels

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 13 Example of a URS for various types of earthquakes (Adopted from FEMA-451B (2003))

of exceedance in 50 years (right column plots) for Thessaloniki and Istanbul derived from their regional hazard curves (left column plots).

The most frequently used return periods are 475 years (corresponding to 10 % probability of exceedance in 50 years; abbreviated as 10 % in 50 years or 10/50) and 2,475 years (corresponding to 2 % probability of exceedance in 50 years, or 2 % in 50 years, or simply 2/50). The latest US hazard maps can be found at the USGS website <http://earthquake.usgs.gov/hazards/>. These maps are updated every few years. The USGS hazard maps have quantitatively revealed important differences between the ground motion characteristics in different regions of the USA. In particular, they illustrate that the difference between the ground motions for 10 %

in 50 years and 2 % in 50 years in Western US (WUS) is in general less than the difference between these two hazard levels in Central and Eastern USA (CEUS).

In the US seismic design, provisions (IBC 2000; FEMA-368 2001; FEMA-450 2003; etc.) provide, as a minimum, a margin of about 1.5 times the design earthquake ground motion (denoted as the light blue curves in spectra in Fig. 16b, c). More specifically, to prevent collapse for a relatively rare but catastrophic event (associated with a 2 % in 50 year probability) to occur and taking into account the approximate minimum seismic margin of 1.5 against collapse, the IBC provisions generally define design ground motion as $1/1.5 (=2/3)$ times the 2 % in 50-year ground motion. In other words, if

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 14 Example of uniform response spectrum generation using probabilistic hazard maps (Adopted from FEMA-451B (2003))

a structure is subjected to a ground motion 1.5 times the standard design level of 10/50, the structure should have a low likelihood of collapse. Certainly, this margin depends on the type of structure, detailing requirements, etc. Nevertheless, this 1.5 factor can be conservative or not depending on the region, e.g., there are important exceptions to this rule, especially near active faults in coastal California.

The plot in Fig. 16a presents several seismic hazard curves for major cities in the USA. The main difference to note is the slope of the curves for WUS compared to CEUS. In particular, for WUS, there is a much smaller increase in seismic demand when shifting to the right side of the plot (from a 10/50 to a 2/50 probability) compared to CEUS. Obviously, frequent occasional and rare events are more probable to happen more often in seismic-prone regions compared to low seismicity regions. Nonetheless, it can be easily noticed that for two regions of low and high seismicity, very rare earthquakes (2/50 and less) may have a similar occurrence rate or even to have a higher probability (but very small in absolute numbers) for the low seismicity regions. Due to the shape of the hazard curves, it can be seen that there is a substantial difference in CEUS between the 500- and 2,500-year hazard levels. Thus, many

buildings in CEUS designed for the 500-year event are vulnerable to collapse in a large, very rare earthquake (a 2,500-year period event).

The plot in Fig. 16b illustrates the UHS for San Francisco, in which the 2/50 and 10/50 spectral curves are shown. Note that, in general, two third times the uniform hazard spectrum for 2 % in 50 years is generally comparable to the design spectrum for 10 % in 50 years (corresponding light blue curve coincides with red curve). On the other hand, the plot in Fig. 16c depicts the UHS for Charleston, South Carolina in EUS, where a severe event (with a magnitude of 7.3) occurred in 1886. The differences are significant, e.g., two third times the spectrum for 2 % in 50 years is much higher than that for 10 % in 50 years. Actually, the 10 % in 50-year spectrum provides roughly one fourth of the corresponding values of 2 % in 50 year spectrum. Note also that the shape of the spectrum is different, having its peak at a shorter spectral period. Conclusively, by comparing hazard curves and UHS in Fig. 16, it can be easily concluded that the two third (2,500-year. EQ) $\approx$ 500-year motions in WUS as suggested by US norms, while in contrast, two third (2,500-year. EQ) $\approx$ 1,600-year motions in EUS. Therefore, in EUS the application of IBC design philosophy leads, to a certain extent, to the

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 15 UHS for 10 % probability of exceedance in 50 years (right column) and PGA hazard curves (left column) for Thessaloniki and Istanbul (Adopted from www.share-eu.org)

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 16 Comparison of hazard curves and UHS in US (Adopted from FEMA-451B (2003))

possibility to overcome a more rare and catastrophic earthquake than the design action of 10/50.

Similar observations can be drawn in other seismic-prone countries. For instance, Fig. 17 illustrates the impact of a change in hazard level in Eastern and Western Canada. More specifically, it depicts $S_a(0.2\text{ s})$ hazard curves for Vancouver and Montreal, showing how increasing the 10 % in 50 years hazard by a factor of two ($2\times$) produces different changes in seismic demand for the two cities. In particular, for Vancouver, this would lead to ground motions with

a 1/2,400 per annum exceedance probability, while for Montreal the ground motions would have a 1/1,600 annual exceedance probability. Clearly, the same level of safety would not be achieved. Even if different constants were used for east and west, the geographical variation across Canada would prevent achieving a constant level of safety for medium to severe hazard levels. Nonetheless, as in the USA, hazard curves indicate that the more severe (2 % in 50 years) hazard level leads to a more uniform seismic demand for the whole country (Ventura 2006).

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 17 Expected ground motion increases with increasing return period (i.e., decreasing probability) in Canada (Adopted from Ventura (2006))

Logic Tree Methods in PSHA

Not all types of uncertainties involved in PSHA can be described by probability distributions, e.g., regarding attenuation relationship, seismicity distribution, etc. In addition, experts may disagree on model parameters, such as fault segmentation, maximum magnitude, etc. Aleatory variability is included directly in the PSHA calculations by means of mathematical integration. Epistemic uncertainty, on the other hand, is included in the PSHA by explicitly including alternative hypotheses and models. Modeling epistemic uncertainty due to imperfect knowledge regarding correct model parameters can be performed through sensitivity analysis or logic tree approaches. The consideration of various seismotectonic scenarios via a logic tree includes multiple alternative hypotheses in a single model, taking into account uncertainties, by explicitly including alternative interpretations, models, parameters, etc., that are weighted according to their probability of being correct.

In general, a “logic tree” consists a classical statistical tool for dealing with this type of assessment problems, in which based of the overall knowledge available, the engineer sets up a number of alternative models and associates to each choice a weight factor representative of his subjective (based on judgment or experience) belief on the validity of the choice. In this manner:

- Each model provides an outcome of the assessment, characterized by a probability

which is the product of the probabilities assigned to the branches of the tree.

- The ensemble of the outcomes provides an approximate discrete distribution of the system’s characteristics, from which statistics such as mean, dispersion, and confidence interval can be obtained.

The US seismic hazard logic tree models can be found in the relevant USGS report (Petersen et al. 2008). An example of a simple logic tree is shown in Fig. 18 (Kramer 1996) having 12 branches in total, as the outcome of $2 \times 2 \times 3$, number of different attenuation, magnitude distributions and maximum value, respectively. Similar logic trees can be created for structural assessment as well as for a kinematic type of seismic hazard. For example, logic tree assessment of fault parameters can be utilized for various fault rupture scenarios of a certain region in order to define more reliably potential exposure of lifelines crossing it (Angell et al. 2003).

Obviously, computational effort increases when increasing number of nodes and branches. Each alternative hypothesis, indicated by a branch of the logic tree, is given a subjective weight corresponding to its assessed likelihood of being correct. Each branch of the logic tree represents alternative hypotheses for the seismic source, earthquake recurrence frequency, ground motion attenuation, and occurrence probability at a site and their weight factors (shown in parentheses). In each “node” of the logic tree, the sum

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 18 Example of a logic tree model (Adopted from Kramer (1996))

of the weight factors is equal to unity, while the outcome of each branch is the product of the weight factors, as shown in the right column of Fig. 18. Hence, final outcome can be obtained as a weighted average of the values obtained at the terminal branches of the logic tree.

Incorporation of Earthquake Return Period in Seismic Norms: The Case of Eurocode 8

In this section, a brief overview will be given regarding the incorporation of earthquake return period into seismic actions as described in the provisions of European seismic design code Eurocode 8 or EC8 (EN 1998), which is composed of six parts:

- EN 1998-1: General rules, seismic actions and rules for buildings
- EN 1998-2: Bridges
- EN 1998-3: Assessment and retrofitting of buildings
- EN 1998-4: Silos, tanks, and pipelines
- EN 1998-5: Foundations, retaining structures, and geotechnical aspects
- EN 1998-6: Towers, masts, and chimneys

This standard provides alternative procedures, values, and recommendations with notes indicating where national choices may be made. Therefore, in each country the National Standard

implementing EC8 should have a National Annex containing all nationally determined parameters and other supplementary guidelines to be used for the design of buildings and civil engineering works. Additionally, as many European countries have very low seismicity, EC8 includes also the provision that in such cases (defined in every National Annex) it is not obligatory to implement seismic design rules.

In general, as prescribed in Eurocode 8 – Part 1 (EN 1998-1) – a new structure in seismic-prone regions is checked against two limit states: the ultimate no-collapse limit state (corresponding to life safety requirement) and the damage limitation limit state (corresponding to damage limitation requirement). Regarding the first limit state, in order to prevent local failures, the design seismic action in terms of reference probability of exceedance in 50 years is $P_{NCR} = 10 \%$ (or for a reference return period of the seismic action equal to $T_{NCR} = 475$ years). These are the recommended values for $P_{NCR} (=10 \%)$ and $T_{NCR} (=475 \text{ years})$; however, each National Annex can ascribe other values. The value of the probability of exceedance, P_R , in T_L years of a specific level of the seismic action is related to the mean return period, T_R , of this level of the seismic action in accordance with Eq. 8 as follows: $T_R = -T_L / \ln(1 - P_R)$. Thus, for a given T_L , the seismic action may equivalently be specified either via its mean return period, T_R , or its probability of exceedance, P_R in T_L years as previously discussed in section “Seismic Hazard Analysis.”

Earthquake Return Period and Its Incorporation into Seismic Actions, Table 1 Importance classes and factors for buildings and reduction factor for damage limitation limit state according to EC8 (EN 1998-1)

Importance class	Building type	Importance factor (γ_I)	Reduction factor (v)
I	Buildings of minor importance for public safety, e.g., agricultural buildings, small warehouses, sheds, barns, etc.	0.8	0.5
II	Ordinary buildings, not belonging in the other categories	1.0	0.5
III	Buildings whose seismic resistance is of importance in view of the consequences associated with a collapse, e.g., schools, assembly halls, cultural institutions, etc.	1.2	0.4
IV	Buildings whose integrity during earthquakes is of vital importance for civil protection, e.g., hospitals, fire stations, power plants, etc.	1.4	0.4

E

Furthermore, the value of importance factor, γ_I (which for buildings can take a maximum value of 1.4), influences the reference seismic action. In particular, the design value of seismic action is equal to $A_{Ed} = \gamma_I \cdot A_{Ek}$, in which A_{Ek} denotes the characteristic value of the seismic action for the reference return period (i.e., peak ground acceleration, a_{gR}). The importance factor $\gamma_I = 1.0$ is associated with a seismic event having the reference return period. A higher importance factor ($\gamma_I > 1.0$) corresponds to a higher value of earthquake return period and vice versa. Through this modification enhanced performance for critical facilities can be achieved compared to conventional structures.

Each importance factor γ_I is assigned to an importance class of structures (see Table 1). Buildings are classified in four importance classes, depending on the consequences of collapse for human life, on their importance for public safety and civil protection in the immediate post-earthquake period, and on the social and economic consequences of collapse. Wherever feasible, this factor should be derived so as to correspond to a higher or a lower value of the return period of the seismic event (with regard to the reference return period) as appropriate for the design of the specific category of structures. Target reliabilities for the no-collapse (and for the damage limitation) requirement are established by the National Authorities for different types of buildings or infrastructure on the basis of the consequences of failure, i.e., by classifying them into proper importance classes. The different levels of reliability are obtained as

mentioned by multiplying the reference seismic action or, when using linear analysis, the corresponding action effects by the matching importance factor.

It is also noted in EC8 that at most sites, the annual rate of exceedance, $H(a_{gR})$, of the reference peak ground acceleration a_{gR} can vary, as a function of a_{gR} , as follows:

$$H(a_{gR}) \approx k_0 \cdot a_{gR}^{-k} \quad (9)$$

in which the value of the exponent k depends on regional seismicity but being generally of the order of 3, as shown in Fig. 19. In addition, to determine the parameter k_0 at least one a_{gR} (or spectral acceleration) value, corresponding to a specific return period, should be known. This value can be obtained from the seismic hazard map for this region for a given $H(a_{gR})$, e.g., 10 % in 50 years or, alternatively, for a certain return period (e.g., $T_{NCR} = 475$ years). Subsequently, using these $H(a_{gR})$ and a_{gR} values (or analogous spectral acceleration data), k_0 can be easily obtained utilizing Eq. 9. Such expressions have been developed in US within SAC/FEMA project (FEMA-350 2000), while recently more efficient second-order hazard approximations have been proposed to capture more closely the curvature of the hazard function (Vamvatsikos 2012).

Furthermore, if the seismic action is defined in terms of the reference peak ground acceleration, a_{gR} , the value of the importance factor γ_I multiplying the reference seismic action to achieve the same probability of exceedance in T_L years as in

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 19 Influence of importance factor on the return period (Adopted from Carvalho (2011))

the T_{LR} years for which the reference seismic action is defined via the following expression:

$$\gamma_I \approx \left(\frac{T_{LR}}{T_L} \right)^{-1/k} \quad (10)$$

Similarly, the value of the importance factor γ_I that needs to multiply the reference seismic action to achieve a value of the probability of exceeding the seismic action, P_L , in T_L years other than the reference probability of exceedance P_{LR} , over the same T_L years, may be estimated as follows:

$$\gamma_I \approx \left(\frac{P_L}{P_{LR}} \right)^{-1/k} \quad (11)$$

For the damage limitation limit state, the values for the probability of exceedance in 10 years and the return period are $P_{DLR} = 10\%$ and $T_{DLR} = 95$ years, respectively. In the absence of more precise information, the seismic action for the verification of the damage limitation requirement is derived from $A_{Ed} (= \gamma_I \cdot A_{Ek})$ using a reduction factor, v , equal to 0.5 or 0.4 to account for the lower return period for damage limitation performance level. As shown in Table 1, this factor depends on the importance class. It is worth noticing that by applying v , the influence of γ_I is reduced compared to the no-collapse limit state, since the differences among the four classes are not so substantial (i.e., multiplying v and γ_I the values of seismic actions are 0.4, 0.5, 0.48, 0.56 for the four classes, respectively). In addition, the seismic action is

slightly less for importance class III compared to class II. The values of v in each country are provided in its National Annex, while different values of v (that can be associated to a certain time interval similarly to γ_I by an exponential expression, analogous to Eq. 10) may be defined for the various seismic zones of each country, depending on the seismic hazard conditions and on the preferred protection level.

The reduction factor, v , is applied on the design seismic action in accordance with limitation of inter-storey drifts as follows (unless otherwise specified):

- For buildings having nonstructural elements of brittle materials attached to the structure, $d_r \cdot v \leq 0.005 h$;
- For buildings having ductile nonstructural elements, $d_r \cdot v \leq 0.0075 h$;
- For buildings having nonstructural elements fixed in a way so as not to interfere with structural deformations or without nonstructural elements, $d_r \cdot v \leq 0.010 h$;

where d_r is the design inter-storey drift and h denotes storey height.

Additionally to the two basic limit states, EC8 implies that a third limit state can be used to check the safety margin against a global structural collapse (Carvalho 2011). In this case, specific measures should be taken to reduce the uncertainty and ensure a robust behavior of the structure, even under seismic actions more severe than the design seismic action of 10/50. This

performance level is implicitly equivalent to the satisfaction of a third performance requirement: prevention of global collapse under a very rare event (having a much higher return period than $T_{\text{NCR}} = 475$ years), equivalently to the 2/50 event of US norms. This performance level is denoted as near collapse (NC) limit state in EC8 Part 3 (EN 1998-3), which is very close to the actual collapse of the structure as it will be discussed in the sequence.

Regarding the other parts of EC8 and their provisions for seismic return periods, EC8 Part 2 for bridges also follows general rules for reference seismic action return period (there are differences, e.g., in importance classes as well as in damage limitation limit state (Fardis et al. 2012), etc.) and also includes informative Annex A with specific details on the reference seismic action and the corresponding return period as well as on the design seismic action during the construction of bridges. EC8 Part 3 (EN 1998-3) for the assessment and retrofitting of buildings provides specific guidelines for the incorporation of return period into seismic actions, which will be presented in a subsequent section. EC8 Part 4 (for silos, tanks, and pipelines), EC8 Part 5 (for foundations, retaining structures, and geotechnical aspects), and EC8 Part 6 (for towers, masts, and chimneys) do not differentiate with respect to return periods and seismic actions with the basic principles and general rules of EC8 Part 1.

Seismic Zones and Representation of the Seismic Action

According to EC8, national territories shall be subdivided by the National Authorities into seismic zones, depending on the local seismicity, while the hazard within each zone is assumed to be constant. For most of the applications of EC8, the hazard is described in terms of a single parameter, i.e., the value of the reference peak ground acceleration on type A ground (i.e., rock), a_{gR} . Additional parameters required for specific types of structures are given in the relevant parts of EC8.

The reference peak ground acceleration on type A ground, a_{gR} , may be derived from zonation maps contained in the National Annex of

each country. The reference peak ground acceleration, chosen by the National Authorities for each seismic zone, corresponds to the reference return period T_{NCR} of the seismic action for the no-collapse requirement (or equivalently the reference probability of exceedance in 50 years, P_{NCR}) chosen by the National Authorities. As aforementioned, the values of γ_I may be different for the various seismic zones of the country, depending on the seismic hazard conditions and on public safety considerations. In general, an importance factor γ_I equal to 1,0 is assigned to the reference return period. For other return period values, the design ground acceleration on type A ground is equal to $a_g = \gamma_I \cdot a_{gR}$.

For instance, the National Annex of Greece uses the default values (10 % in 50 years event, etc.) and divides the country into three zones, in which the seismic action, A_{Ek} , in terms of a_{gR} is set equal to: 0.16 g, 0.24 g, 0.36 g, for zones Z1, Z2, and Z3, respectively. An objective of the future updating of EC8 (Carvalho 2011) is to create European zonation maps with spectral values for different hazard levels, similar to provisions in the USA. As aforementioned, such European hazard maps have been recently developed for various return periods, within SHARE project (www.share-eu.org), as the one for 10/50 (475 years return period) mean PGA values shown in Fig. 20.

In EC8 the earthquake motion at a site is represented by an elastic response spectrum in terms of spectral acceleration values (Annex A of EC8 Part 1 additionally represents seismic action in the form of an elastic displacement response spectrum). The shape of the elastic response spectrum for each country may be found in its National Annex, and it is the same for the two levels of seismic performance, i.e., for the no-collapse requirement as well as for the damage limitation requirement. It is also noted that in selecting the appropriate shape of the spectrum, consideration should be given to the magnitude of earthquakes that contribute most to the seismic hazard as defined in PSHA, rather than on conservative upper limits (e.g., the maximum credible earthquake). Regarding magnitude, two types of spectra are recommended,

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 20 PGA mean values in Europe for 475 years return period (Adopted from Giardini et al. (2013))

type 1 for magnitude bigger than 5.5 and type 2 for smaller earthquakes. These two types have the same pattern but different spectral amplifications factors that depend also on the stromatography (of the top 30 m surface layer) of the examined region. EC8 provides also recommendations for the vertical acceleration response spectra.

When the earthquakes affecting a site are generated by widely differing sources, the possibility of using more than one spectrum, each having different pattern, should be considered to enable the design seismic action to be adequately represented. In such circumstances, different values of a_g will be required for each type of spectrum and earthquake. Furthermore, for important structures ($\gamma_I > 1.0$), topographic amplification effects should be taken into account, as described in Informative Annex A of EC8 Part 5 (EN 1998-5). Finally, it is also stated that time histories (at least three

accelerograms) representative of the earthquake motion may be used in certain cases, taking into account spatial variability whenever needed.

Return Periods in EC8 Part 2

As aforementioned EC8 Part 2 contains Informative Annex A that defines probabilities related to the reference seismic action as well as guidance for the selection of design seismic action during the construction phase of a bridge. In particular, the reference seismic action can be defined by selecting an acceptably low probability, p , that it can be exceeded within the design life, t_L , of the bridge. Therefore, the return period of the event, T_R , is given by

$$T_R = 1 / \left(1 - (1 - p)^{1/t_L} \right) \quad (12)$$

The reference seismic action (corresponding to $\gamma_I = 1.0$) usually reflects a seismic event with

a reference return period, T_{NCR} , of 475 years. Such an event has a probability of exceedance between 0.10 and 0.19 for a design life ranging between 50 and 100 years, respectively. This level of design action is applicable to the majority of the bridges of average importance.

Regarding the design seismic action for the construction phase, assuming that t_c is the duration of the construction phase of a bridge and p is the acceptable probability of exceedance of the design seismic event during this phase, the return period T_{Rc} is given by Eq. 12, using t_c instead of t_L . For the relatively small values usually associated with t_c ($t_c \leq 5$ years), expression Eq. 12 may be approximated by the following simpler relationship: $T_{Rc} = t_c/p$, while it is recommended that the value of p does not exceed 0.05.

The value of the design ground acceleration, a_{gc} , corresponding to a return period, T_{Rc} , depends on the seismicity of the region. In many cases the following relationship offers an acceptable approximation:

$$\frac{a_{gc}}{a_{gR}} = \left(\frac{T_{Rc}}{T_{NCR}} \right)^k \quad (13)$$

where a_{gR} is the reference peak ground acceleration corresponding to the reference return period T_{NCR} . The value of the exponent k depends on the seismicity of the region, and values in the range of 0.30–0.40 can be used. Finally, it is stated that the robustness of all partial bridge structures should be ensured during the construction phases independently of the design seismic actions.

Limit States and Return Periods in EC8 Part 3

As prescribed in Eurocode 8 Part 3 (EN 1998-3), a retrofitted existing structure is checked against three limit states (LS), namely, near collapse (NC), significant damage (SD), and damage limitation (DL). Note that the definition of the LS of near collapse given in Part 3 of EC 8 is closer to the actual collapse of the building than the one given in Part 1 of EC 8 and corresponds to the maximum exploitation of the deformation capacity of the structural elements. Actually, the LS associated with the “no-collapse” requirement in

Part 1 is roughly equivalent to the one that is defined as LS of significant damage in Part 3.

The National Authorities decide whether all three or less (and which) limit states shall be checked, as defined in National Annex. The appropriate levels of protection are achieved by selecting, for each of the aforementioned LS, a proper return period for the seismic action. The return periods ascribed to the various LS to be checked in a country may be found in its National Annex. The protection is normally considered appropriate for ordinary buildings by selecting the following values for the corresponding return periods:

- LS of near collapse (NC): 2,475 years, corresponding to a probability of exceedance of 2 % in 50 years
- LS of significant damage (SD): 475 years, corresponding to a probability of exceedance of 10 % in 50 years
- LS of damage limitation (DL): 225 years, corresponding to a probability of exceedance of 20 % in 50 years

For instance, the Greek code (KANEPE 2012) for structural interventions on reinforced concrete buildings, after harmonization with Eurocode 8 Part 3, defines two hazard levels. The first has probability of exceedance of 50 % (maximum tolerable) in 50 years and corresponds to an average return period of 70 years, while the second has a probability of exceedance of 10 % in 50 years that corresponds to a 475 years return period. For the 10/50 level, the design seismic action of EC8 Part 1 is taken into account, while for the 50/50 level, 60 % of the design seismic action of EC8 Part 1 is taken into account. It is also stated that a Public Authority shall define the cases where a 50 % probability of exceedance within the reference 50-year period will not be allowed.

Seismic Actions in Performance-Based Design

Severe damages caused by recent earthquakes in seismic-prone areas made the engineering

Earthquake Return Period and Its Incorporation into Seismic Actions, Table 2 Various performance and hazard levels in a typical PBD framework

		Design Performance Level

	10% / 50years (mean return period 475 years)			
	2% / 50years (mean return period 2475 years)	Performance Objectives for Emergency Response Facilities		

community to question the effectiveness of contemporary seismic design codes. In general, in strong events the economic losses were vast, while in many cases the losses in terms of human lives were also excessive, especially in developing countries. Given that the primary goal of contemporary seismic design is the protection of human life, it is evident that additional performance targets should be considered. Under this perspective, performance-based design (PBD) has been quite recently introduced in earthquake engineering and guidelines (SEAOC 1995; FEMA-273 1997; FEMA-356 2000; FEMA-445 2006). PBD is a holistic framework that includes: local site conditions examination; development of conceptual, preliminary, and final design stages; and construction and maintenance of the building over its life to ensure reliable and predictable seismic performance under varying demand conditions. Consequently, the structure is designed to withstand certain earthquake hazard levels with a predefined behavior for each case.

According to PBD procedures, the structures should be able to resist earthquakes in a quantifiable manner and to present specific levels of possible damages. They are multilevel design approaches, where various levels of

hazard and structural performance are considered. In PBD more accurate analysis procedures are usually employed compared to conventional seismic design to represent more accurately the nonlinear structural response for higher seismic intensities. PBD has the following distinctive characteristics with respect to the prescriptive design codes: (i) it allows the owner and the engineer to choose both the appropriate level of seismic hazard and the corresponding performance level of the structure, and (ii) the structure is designed to meet a series of combinations of hazard levels with corresponding performance levels. As shown in PBD illustrative Table 2, the horizontal axis represents step by step to the right structural performance degradation, while in the vertical axis the size of earthquake increases as we move downward. Although several hazard and performance levels have been proposed, the 3 × 3 PBD framework as the one shown in Table 2 is considered as more effective (e.g., Elnashai and Di Sarno (2008)).

The first step in a performance-based seismic design procedure is the definition of the performance objectives that will be used. One performance objective is defined as the combination of a certain performance level for a specific hazard

level. Typical structural design performance levels are the following:

- (i) *Operational* performance level: the structure retains its strength and stiffness as the overall damage level is very light and none permanent drift is observed. Only minor cracking in facades, partitions, and ceilings are encountered, while all components that are important to normal operation are functional. A green placard will be placed in the building by post-damage inspectors.
- (ii) *Life safety* performance level: the overall damage level is characterized as moderate, i.e., some structural elements and components may be damaged and permanent drifts may be encountered. Nevertheless, structural elements in all stories maintain a considerable residual strength and stiffness and gravity load-bearing elements continue to function. Injuries may occur, however, the overall risk for casualties due to structural damage is low. The damaged structure shouldn't be at imminent collapse risk, but certainly temporary supports and structural repairs will be necessary prior to re-occupancy (i.e., it should be possible to repair the structure although this may not be economical). A yellow placard will be placed in the building by post-damage inspectors.
- (iii) *Collapse prevention* performance level: the structure is heavily damaged and has large permanent drifts. Structural elements have low residual lateral strength and stiffness, although vertical elements are still capable of sustaining gravity loads. Most nonstructural components have collapsed. The structure is near collapse, and most probably it will not be techno-economically practical and safe to repair and reuse it. A red placard will be placed in the building by post-damage inspectors.

The first level aims to maintain structural stiffness, the second is focused on strength, and the last one aims to exploit ductility of the system.

Under this perspective, the structural response is altered from initial elastic to limited and highly nonlinear for the last two performance levels, respectively.

An initial *fully operational* performance level can also be used as the first performance state in a PBD framework, if no damage is allowed to structural and nonstructural components and full functionality of the structure is maintained without any repairs. An additional performance level, the so-called damage limitation, can also be used in PBD as an intermediate state between *operational* and *life safety* performance levels. In this state, the structure may be only slightly damaged having negligible permanent drifts. Structural elements retain their strength and stiffness properties, do not have any significant yielding, and do not need any repair measures. Nonstructural components, such as partitions and infills, may have several cracks; however, such damages could be economically repaired.

The second step in a performance-based seismic design procedure is to determine the earthquake hazard levels. Earthquake-related hazards include mainly ground shaking but also – in certain cases as aforementioned in section “[Seismic Hazard Analysis](#)” – various kinematic distress types (fault rupture, liquefaction, lateral spreading, and landslides). For instance, soil liquefaction hazard in a PBD perspective has been presented by (Kramer and Mayfield 2007) to compare likelihood of liquefaction occurrence for different seismicity level (associated with earthquake return period).

Typically, ground shaking is the earthquake hazard that provisions of the seismic design norms directly address, and it is also the focus of this work. As described in section “[Seismic Hazard Analysis](#),” ground shaking (as well as any other type of) hazard is usually characterized by a hazard curve, which indicates the probability that a given value of a ground motion parameter, for example, peak ground acceleration, will be exceeded over a certain period of time. Hence, the earthquake design levels are expressed in terms of a mean recurrence interval or a probability of exceedance for a specified

Earthquake Return Period and Its Incorporation into Seismic Actions, Table 3 PGA hazard levels (50/50 and 10/50) in Greece utilizing (Papazachos et al. 1993) approach

Seismic zones	Parameters		Occasional (recurrence interval 72 years or 50 % in 50 years)	Rare (recurrence interval 475 years or 10 % in 50 years)
	B ₁	B ₂	PGA (g)	PGA (g)
Zone I	3.28	0.61	0.08	0.14
Zone II	3.64	0.64	0.13	0.215
Zone III	4.01	0.61	0.17	0.29
Zone IV	4.64	0.55	0.29	0.46

number of years that covers the design life of the structure, e.g., typically 50 years for buildings. The most commonly used ground shaking hazard levels are the following:

- (iv) *Occasional* hazard level: with probability of exceedance 50 % in 50 years with recurrence interval equal to 72 years and annual probability of exceedance approximately equal to 1.4 %. This level is the so-called serviceability earthquake (SE), which is approximately 0.5 times the design earthquake (DE) (ATC-40 1996).
- (v) *Rare* hazard level: with probability of exceedance 10 % in 50 years with recurrence interval equal to 475 years and annual probability of exceedance approximately equal to 0.2 %. This level is the so-called design earthquake (DE) or design basis earthquake (DBE), and (as aforementioned in section “[Seismic Hazard Analysis](#)”) for certain norms, it is approximately the two third of the more severe 2/50 level.
- (vi) *Maximum considered event* hazard level: with probability of exceedance 2 % in 50 years with recurrence interval equal to 2,475 years and annual probability of exceedance approximately equal to 0.04 %. This level is the so-called maximum considered earthquake (MCE).

According to the adopted PBD formulation (e.g., SEAOC (1999)), other hazard levels can also be used. For instance, a *frequent event* hazard level having a very low return period (i.e., 43 years or probability of exceedance 50 % in 30 years, or 2.3 % annual probability of

exceedance) or a *very rare event* hazard level having an intermediate return period (i.e., 970 years, or probability of exceedance 10 % in 100 years, or 0.1 % annual probability of exceedance) between the two higher ones. In addition, it is worth noticing the distinction among maximum earthquake (ME) level and maximum considered earthquake (MCE) (ATC-40 1996). The ME is deterministically defined as the maximum level of ground shaking that may ever be expected at the construction site based on regional seismotectonic data. If ME is expressed in probabilistic terms, as the aforementioned hazard levels, then it has a return period of about 1,000 years; thus, it is equivalent to *very rare event* hazard level.

The above hazard levels can be associated to major seismic demand parameters, such as the peak ground acceleration (PGA). For instance, in the study by Papazachos et al. (1993), Greece was divided into four zones, and based on this work, Table 3 depicts the PGA levels for two return periods, T_R , utilizing the following log-linear formula:

$$SI = B_1 + B_2 \cdot \log T_R \quad (14)$$

in which SI denotes a characteristic measure of the seismic intensity (macroseismic intensity or the logarithm of strong ground motion parameters, such as PGA or PGV), and parameters B_1 and B_2 vary for each SI.

Such relationships can be derived based on a Cornell-type attenuation formula of the form (Papazachos et al. 1993)

$$SI = C_1 + C_2 \cdot M - C_3 \cdot \ln(D + C_4) \quad (15)$$

in which M is the earthquake magnitude, D is the epicentral or hypocentral distance, and C_1 , C_2 , C_3 , and C_4 are regional constants. Based on such formulations, updated seismic hazard maps (10/50 and 10/100) for Greece have been constructed (Papaioannou et al. 2008). Alternative relationships for PGA and T_R for design earthquakes in Greece have been recently proposed, utilizing a uniform reliability index approach (Makarios 2013).

In addition, spectral values (accelerations or displacements) taken from a design spectrum obtained for a specific return period (e.g., for reference $T_{NCR} = 475$ years and $S_{10/50}$ spectral values) can be used to obtain approximate spectral values for other return periods utilizing an expression similar to Eq. 13 of EC8 Part 2 for bridges, based on SEAOC (1999) as follows (Kanellopoulos 2007):

$$\frac{S_x}{S_{10/50}} = \left(\frac{T_x}{T_{NCR} = 475} \right)^n \quad (16)$$

where n depends on regional seismotectonic characteristics and depends on the hazard level. For example, for California and lower hazard levels, $n = 0.44$ and for severe events $n = 0.29$; thus, if $Sa_{10/50} = Sa(T = 0) = PGA_{10/50} = 0.30$ g, then for $T_x = 72$ years utilizing Eq. 16 it can be easily derived that, for $n = 0.44$, $Sa_{50/50} = Sa(T = 0) = PGA_{50/50} = 0.13$ g.

Return period can also be used for the assessment of structural capacity and vulnerability of a structure in order to design proper mitigation measures. In other words, it can be used to quantify the safety levels and structural deficiencies in a more straightforward manner and to assess the improvement of structural performance after certain retrofitting interventions. For this purpose, Raffaele and Fiore (2013) presented a simple methodology (based on the reverse application of the well-known N2 method) that allows the assessment of the return period when the elastic period and the capacity of the examined structure for a given limit state are available. Subsequently, this so-called “capacitive” return period can be used to determine the seismic capacity and the reference life for any limit state considered.

Structural Performance Assessment in PBD

The main objective of multistep PBD procedures is to define a relation between the seismic intensity level and the corresponding maximum response quantity of the structural system. The intensity level and the structural response are described via suitable intensity measures (IM) and engineering demand parameters (EDP), respectively. Since EDPs actually represent the level of structural damage, they are usually utilized in the form of various damage indices (DI). Very frequently in seismic assessment of buildings, the maximum inter-storey drift and maximum floor acceleration are chosen as they can be directly associated with structural performance levels.

Elnashai and Di Sarno (2008) have presented a very well-established direct association of the structural performance levels with earthquake hazard level (in terms of magnitude and return period), structural characteristics as well as engineering and socioeconomic limit state characterizations (i.e., drifts, damage levels, etc.). In other studies, earthquake return periods have been directly used in presenting and comparing (in terms of EDPs) the performance of different structural configurations, e.g., the height-wise distribution of inter-storey drifts and peak floor accelerations for fixed base vs. isolated buildings (Chimamphant and Kasai 2013).

Despite the continuous advances in computational methods as well as in software and hardware, nonlinear time-history analyses are not widely used in engineering practice, and seismic norms suggest to employ them in special cases. In contrast, a nonlinear static procedure, the so-called “pushover” method, is very frequently used for seismic performance assessment of structures. A schematic representation of a typical pushover curve and its utilization in PBD framework based on the hazard level is shown in Fig. 21. The major steps of the whole evaluation process for each hazard level are depicted in Fig. 22.

It is worth mentioning that in recent years PBD has also been integrated into optimization approaches, in some of which (e.g., Fragiadakis and Papadrakakis (2008)) the aforementioned

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 21 Seismic performance assessment based on pushover analysis (Adopted from <http://peer.berkeley.edu>)

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 22 Basic steps in performance evaluation (Adopted from FEMA-451B (2003))

recurrence periods of PBD hazard levels have been used as probabilistic constraints in the optimization process. Life cycle cost analysis (LCCA) is also considered nowadays in conjunction with PBD and optimization to achieve best possible solutions. LCC represents the total cost, including that related to the expected damages caused by earthquake events that may occur during the design life of the structure. It has been proven that the objective to satisfy all checks imposed by contemporary norms aiming to minimize initial construction cost is not always efficient in terms of overall long-term

cost and safety. In a holistic probabilistic LCCA and PBD framework, all aspects are considered, and the outcome is given in terms of fragility curves and loss hazard curves. As shown in Fig. 23, the latter are similar to seismic hazard curves (e.g., Fig. 4), as the losses (or repair cost), expressed in terms of monetary units, and are also associated to earthquake return periods or probabilities of exceedance.

To accomplish this goal, it is necessary to obtain curves illustrating the so-called mean annual frequencies (MAF) of exceedance for

Earthquake Return Period and Its Incorporation into Seismic Actions,

Fig. 23 Characteristic repair loss curve for various hazard levels

different performance levels. For this purpose, as aforementioned in seismic hazard analysis section, based on Poisson's stochastic model to describe earthquake occurrence, the probabilities for damage indices (DI) (e.g., drifts, maximum accelerations, etc.) are calculated as follows:

$$P(DI > DI_i) = -\frac{1}{\lambda \cdot t} \cdot \ln(1 - P_t(DI > DI_i)) \quad (17)$$

in which $P_t(DI > DI_i)$ is the exceedance probability over a period $[0, t]$, λ is the annual earthquake occurrence rate, and t is the functioning period (typically 50 years) of a new structure or the remaining life of an existing one. In order to calculate $P(DI > DI_i)$, it is necessary to evaluate the t -year exceedance probability $P_t(DI > DI_i)$. For $t = 1$ year, the annual exceedance probability $\bar{P}_i(DI > DI_i)$ is obtained for the three most commonly used PBD earthquake hazard levels (as aforementioned, having exceedance probabilities: 2 %, 10 %, and 50 % in 50 years, or in terms of annual exceedance probabilities approximately equal to 0.04 %, 0.2 %, and 1.4 %, respectively), and the maximum values of the chosen DIs are calculated.

Consequently, the maximum DIs calculated at each hazard level have an annual exceedance probability equal to that of the hazard level. In this manner, one common curve can be constructed for all hazard levels using pairs of maximum DIs and their respective annual exceedance

Earthquake Return Period and Its Incorporation into Seismic Actions, Fig. 24 Best fitting of annual probabilities and damage indices for various hazard levels

probabilities, based on an exponential formula of the form (Lagaros and Mitropoulou 2013):

$$\bar{P}_i(DI > DI_i) = \gamma \cdot (DI_i)^{-k} \quad (18)$$

where k represents the hazard decay and γ is a scale factor. Mathematically, k is the slope of the hazard curve and indicates the way that ground motion gets more intense as the probability of exceedance decreases. Parameters γ and k are obtained by a best fitted curve (as the one shown in Fig. 24), which is the outcome of the available $\bar{P}_i$ and DI_i pairs for each of the examined DIs. Subsequently, for each i th limit state, the annual exceedance probability of DI_i , $\bar{P}_i(DI > DI_i)$ can be easily derived from this curve.

Closure

According to contemporary seismic norms and engineering practice worldwide, seismic design is performed for the functioning period of a structure, depending on its importance and use, for different limit states, very frequently defined in terms of the return periods of seismic actions. The most commonly used seismic intensity measures include: earthquake magnitude and energy as well as number of earthquakes above a certain magnitude per year(s) and the probability of exceedance, annually or in a specified time interval, or the return period of such event. Based on these data, when designing a new structure or when assessing an existing one, seismic hazard and seismic risk can be evaluated. As aforementioned, seismic hazard defines the expected occurrence of future seismic events, while seismic risk describes the expected consequences. There are two methods for the assessment of seismic hazard: deterministic (DSHA), magnitude “ x ” earthquake due to “ y ” fault, and probabilistic (PSHA), “ x ” % probability of exceedance in “ y ” years of the design ground shaking level.

Since hazard analysis should incorporate uncertainties related to seismic ground motions parameter and their modeling, PSHA is the most popular choice. The uncertainties considered in PSHA are the maximum magnitude, earthquake recurrence rate, seismic source characteristics, attenuation relationships, effects of local site conditions, etc. PSHA is used for the calculation of the mean hazard curve (MHC) utilizing the Poisson model to predict the probability of earthquakes based on the average rate of earthquakes of a given size that occur in a region. Such curves provide the annual probability or recurrence period that a seismic ground motion exceeds a particular level at the specific region.

Structural capacity and demand depend on the excitation characteristics and structural properties. Typically, engineers consider the performance of a structural system for a given period of time. The demand, such as structure’s global drift, is clearly a quantity that fluctuates in time and is highly uncertain depending on the seismic

excitation during a certain time period. The capacity characterizes the system and also depends on the imposed seismic demand. It is a common practice to use the maximum response or seismic distress over a given time period (annual or per 50 years) as the demand variable. For example, a 10 % probability of exceedance in 50 years is used worldwide as the threshold for selecting the design earthquake parameters.

Seismic intensity is typically expressed by means of spectral acceleration or peak ground acceleration. According to the contemporary PBD perspective, depending on the seismic intensity or ground motion return period, different (and often not negligible) levels of structural damage and, consequently, repairing costs shall be expected and accepted as a result of the nonlinear structural response. In this context, the specification of each performance objective is given for each pair of hazard level (x % in 50 years) and an acceptable performance level (i.e., maximum acceptable damage if that event occurs) depending on the importance of the structure.

Summary

Seismic hazard (related to ground shaking, fault movement, etc.), is a natural threat that can produce adverse effects to buildings and infrastructure. On the other hand, seismic risk defines the probability of the consequences of an earthquake, such as structural damage, will be equal or exceed a target value for a given period of time. In other words, risk is defined as the product of the hazard and the exposure of structures to the hazard, while the latter is directly related to structural vulnerability. Very frequently magnitude and other seismic intensity parameters are associated with earthquake return period which depends on the seismotectonic conditions of the examined region. Ground motion intensity at a site depends on proximity of sources and other earthquake source effects including travel path effects and local site conditions. Site conditions (stromatography, subsurface bedrock morphology (basin effects), surface topography) can

have a significant effect on ground shaking and structural response. Relative distance of the site to the fault is also important and is usually incorporated in the form of ground motion attenuation relationships that consider source effects, travel path effects, and local site effects (at least basic ground condition, e.g., rock or soil) and also take into account various uncertainties. There are two types of uncertainties related to seismic hazard: (i) epistemic uncertainties due to incomplete knowledge about natural phenomena, which affects our ability to model them, and (ii) aleatory uncertainties that include any inherent randomness which arises from physical variability of the natural process. There are two basic methods for performing seismic hazard assessment: deterministic seismic hazard assessment (DSHA) and probabilistic seismic hazard assessment (PSHA). The latter is the most commonly used in contemporary norms and engineering practice, in which seismic hazard is expressed in terms of mean recurrence of events, the so-called return period, or the probability of exceeding a certain seismic intensity level over a given time period. The return period (e.g., typically 475 years for design basis earthquake) defines the average time interval to have events (not only earthquakes but floods, hurricanes, etc.) of a certain or greater severity. Alternatively, the probability of exceedance (e.g., typically 10 % in 50 years for design basis earthquake) is a statistical representation of the likelihood that earthquake effects of a certain level will be experienced at the site of interest within the prescribed number of years. With proper statistical models these two parameters are directly related and are equivalently used. In this work, a brief overview of these methodologies will be given in order to illustrate the incorporation of earthquake return period into seismic actions on structures due to ground shaking. More specifically, the focus will be given on contemporary seismic norms, such as the European seismic design code (Eurocode 8), as well as performance-based design (PBD) framework, in which the probabilities of exceeding performance criteria is directly related to probabilities of various seismic events occurrence in terms of their return period.

Introduction

Lifelines and critical facilities refer to the complex system and network assets of connected components usually interacting with other components and systems, which are performing vital functions that are essential to sustain the life and the growth of a community, such as producing, transporting, and distributing goods or services. Their global value for the society and economy is permanently increased in our modern, technologically advanced, highly demanding, and fragile world. In case of strong earthquake motions, their physical damages and the consequent disruption of the services they provide may contribute seriously to the global economic losses. At the same time, their restoration cost may be very high, reaching in several cases to 10 %, 15 %, or even more in some extreme cases (e.g., the water system in Christchurch, New Zealand) of the initial construction cost of the whole system they belong. Therefore, in terms of resilience, it is important to recognize and quantify the seismic

risk and global losses associated to damages of lifelines and critical facilities and establish efficient seismic risk mitigation strategies. Mitigation actions include, among others, enhancement of emergency preparedness, strengthening of existing structures, upgrade of seismic design guidelines, and standards and improvement of the recovery planning.

The issue of resilience of lifelines and critical facilities is of utmost priority for the preparedness and mitigation of seismic risk; a good evaluation of the resilience of the lifelines for different seismic scenarios and the implementation of pro-seismic actions to improve it are of major importance. In other words, lifeline companies, public administration, and community need to be “prepared” and less “vulnerable,” in order to achieve a high “resilience.” In the last years, as the idea of the necessity of building disaster resilient communities gains acceptance, new methods have been proposed to quantify resilience beyond estimating losses. Because of the vastness of the definition, resilience necessarily has to take into account its entire complex and multiple dimensions, which includes technical, organizational, social, and economic facets (Cimellaro et al. 2010).

Lifelines may be distinguished in two major categories: (i) utility systems including potable water, wastewater, natural gas, oil, electric power, and communication and (ii) transportation systems comprising roadways, railways, airport, and port facilities. Sometimes the terms infrastructures or critical facilities are used instead, at least for some of them. Lifeline systems present three distinctive features: (a) spatial variability and exposure to different geological and geotechnical conditions and hazards (e.g., fault crossing, landslides, liquefaction); (b) wide variety of component typologies and materials used; and (c) specific functionality requirements, which makes them highly hierarchical networks. For practical reasons, they are generally distinguished to links (e.g., pipelines, roads) and nodes (e.g., tanks, power substations, bridges).

An important issue in understanding and defining the risk mitigation of lifelines and critical facilities is the extensive interdependencies

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 1 Example of infrastructure interdependencies (Modified, Rinaldi et al. 2001)

within utility networks and infrastructures as well as infrastructure business, which are schematically shown in Fig. 1. Infrastructure outages due to seismic damages can cascade through the economy and considerably increase the overall losses. Moreover, interactions between systems can severely impact the emergency response, especially when the disruptions concern critical facilities, such as hospitals, command centers, etc. Therefore, the key interactions should be recognized and considered in the risk mitigation planning.

Several devastating earthquakes occurred during the last century, causing extensive losses in terms of fatalities, injuries, damages, and disruptions. The experiences from past earthquakes show that the short- and long-term economic impact due to damages of lifelines can be significant. In a recent study by CATDAT (Daniell and Vervaeck 2013), the disaggregation of direct economic losses of 61 selected major earthquakes

from 1900 to 2012 showed that around 30 % of the direct losses came from infrastructure losses in transport, communications, pipelines, energy supply systems, etc. Knowledge, experience, and lessons learned from past earthquakes have significantly contributed to understanding the structural and functional behavior of lifelines and critical facilities and to develop more appropriate methods and tools toward effective risk mitigation.

The lessons learned from past earthquakes also concern the readiness of lifeline companies and authorities to restore damages as well as to understand the interactions between different systems. In 1989 M_w 6.9 Loma Prieta earthquake, the damages occurred in the water network greatly affected the firefighting capacity in the area of San Francisco, Oakland, and Berkeley. In 1994 M_w 6.7 Northridge earthquake, all of the 1.5 million power customers and about 50,000 water customers lost service, many for a week or

more (Schiff 1995). Earthquake-related damage to electric power systems can cause considerable direct repair and restoration costs, business interruption, inconvenience, and permanent loss of data, food, and perishable goods. Similarly, earthquake damage to water supply systems can have serious economic and health consequences. After the 1995 M_w 6.8 Hyogoken-Nanbu earthquake, it was observed that the restoration period of water system in Kobe was much longer compared to other major earthquakes due to traffic congestion, street blockades, damaged buildings, and water that flowed into gas pipelines (Kameda 2000). In general, the functional restoration for the damaged networks in Kobe needed five to ten times more time than those experienced in other major earthquakes. The final recovery period in Kobe was 82 days for water supply, 85 days for natural gas supply, 7 days for power supply, 20 months for highway bridges, 6 months for major lines of railways, and about 2 years for the main port facilities.

Main Actions for Risk Mitigation of Lifelines and Critical Facilities

The general mitigation framework of lifelines and critical facilities includes the following main actions: risk assessment (1), risk reduction (2), readiness for emergency response (3), and readiness for recovery (4). Each of these actions is shortly described in the next paragraphs.

1. **Risk assessment** The estimation of seismic risk is the fundamental step in risk management and decision-making for risk mitigation. Risk assessment refers to the probable future losses (physical, performance, economic, social) not only due to structural damages but also considering the business interruption or interdependencies of lifelines. Lifeline companies and civil protection authorities are asked to determine how to best allocate the limited resources for risk reduction measures (actions 2, 3, and 4) based on the results of seismic risk analyses for their facilities and the

selection of “acceptable” risk. Still the decision by itself is very challenging, because seismic risk assessment includes various uncertainties related to seismic hazard, vulnerability, performance, and loss estimation procedures. Moreover the selection of acceptable risk needs appropriate balance between cost, risk, and benefits, which is different for each network and society.

Seismic hazard and therefore seismic risk are considered as variable in space and time. Risk assessment in different time scales is illustrated in Fig. 2 with reference to the occurrence of a disastrous earthquake. Examples of mitigation actions appropriate for each time period are also given. Long-term assessment is based on the seismic hazard model providing, for example, PGA values for outcrop rock conditions with 475 mean return period for Euro-Mediterranean region (Giardini et al. 2013). Such maps can be used for the risk assessment of common structures; for essential facilities (e.g., communication towers, hospitals, major bridges), the hazard assessment and risk require longer return periods (e.g., up to 5000 years). Short to medium term hazard and risk assessment may also be computed often using defined scenario type earthquakes.

Recent technological advances in seismic instrumentation and telecommunication permit the implementation of early warning systems (Fig. 2c) and real-time hazard and risk assessments (Fig. 2d), which are related to the emergency response actions in the co-seismic phase (Gasparini et al. 2007; Allen et al. 2009; Zschau et al. 2009; Allen 2011; Erdik and Fahjan 2006). They involve the generation of alarm signals directly from online instrumental data and the generation at a first stage of real-time ground estimation maps and in the second stage the vulnerability and risk assessment of structures provided that fragility curves are available. The alarm signals alert for the coming earthquake in a time window of *few seconds* and enable safe shutdown of critical facilities (e.g., nuclear plants, gas network) or train and traffic stopping systems.

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 2 Risk assessment and examples of mitigation actions in different time scales with reference to the occurrence of a disastrous earthquake (EQ)

The assessment of ground shaking intensity maps and/or physical damage and casualties takes part immediately after earthquake (*few minutes/hours*) and assists the lifeline owners and stakeholders for the emergency actions (rapid response system). In this way the impact of a disastrous earthquake can be reduced due to timely and effective operations (e.g., allocation of resources and prioritization of interventions). Such dense strong ground motion monitoring systems capable of computing damage and casualties in near real time have been implemented in regional or city scale in California, Yokohama, Tokyo, Istanbul, Taiwan, Bucharest, and Naples (Erdik and Fahjan 2006). In other cases, early warning systems are implemented for the monitoring of individual structures and critical facilities (see REAKT project, <http://www.reaktproject.eu/>).

Finally, a critical issue in the risk management and reduction of impact after a seismic event is to assess the functionality of mainshock damaged infrastructures (e.g., major bridges, hospitals) considering the aftershock hazard (Fig. 2e). This is a challenging issue due to limited time availability (*days/months*), the lack of adequate models for the fragility assessment of damaged structures, and the inherent uncertainties in aftershock hazard assessment.

2. **Risk reduction** is related to the identification of the components or parts of the networks and infrastructures that present particular vulnerability and can result to high loss of network performance due to seismic damages. The definition of priorities for retrofitting should be based on vulnerability and risk assessment studies. Specific risk reduction measures should be taken before the earthquake in

Earthquake Risk Mitigation of Lifelines and Critical Facilities,

Fig. 3 Fragility curves for a five spans bridge, with an expansion joint in the center span, supported by four columns, before and after retrofit (Kim and Shinozuka 2004)

order to improve the seismic performance of infrastructure assets. These include the following:

- **Strengthening of vulnerable infrastructure assets** to improve their seismic performance. Several utility systems and networks are now outdated and often without proper seismic design and protection, as, for example, parts of water and wastewater systems in several cities were built more than a century ago. State-of-the-art technical guidelines for seismic assessment, retrofit, and rehabilitation have been published around the world, with emphasis to buildings. Retrofitting techniques are generally case dependent and the description of their typologies is beyond the present essay. Few typical examples are given below:

Geo-structures: Stabilization of embankments, retaining walls, and steep natural slopes; ground improvement, especially in case of liquefaction susceptibility.

Pipelines and wastewater networks: Replacement of vulnerable segments, upgrade of valves, local ground improvement, and increase of dead load of the pipes in particular in liquefaction-prone areas.

Bridges: Retrofitting for continuity to multiple simple spans through restrainers

and/or shear blocks; replacement of old bearings with ductile, multi-rotational, and multidirectional bearings; retrofitting of concrete columns with insufficient confinement through steel jacketing to provide passive confinement. Several studies have been conducted showing the effect of retrofitting. An example is shown in Fig. 3, where the effect of retrofit by means of steel jacketing of columns is illustrated in the fragility curves of typical bridges in southern California. In the USA, the Federal Highway Administration (FHWA) has published a manual including most current state of practice in assessing the vulnerability of highway structures to the effects of earthquakes and implementing retrofit measures to improve performance (FHWA 2004, 2006).

- **Undertake countermeasures against geotechnical hazards** such as liquefaction (later spreading, settlement) and landslides/rockfalls or **other induced phenomena** such as the tsunami waves (e.g., protecting walls).
- **Improve the design and construction practices** for new lifeline components. The design of critical infrastructures should be based on advanced and detailed seismic

hazard analyses, considering the topographical and geotechnical conditions of the site at local or regional scale. Soil-foundation-structure interaction effects are of high importance and should be considered in the design of critical infrastructures (e.g., major bridges). The uses of special materials and techniques that improve the seismic performance of structures (e.g., ductile materials for pipelines, soil-rubber mixtures for embankments) and the use of base isolation systems are other practices for seismic risk reduction of several lifeline components.

- **Relocate components** if this is cost beneficial or more feasible instead of taking large-scale strengthening countermeasures, for example, to stabilize landslide zones. The case of active seismic fault crossing is another typical example where sometimes relocation of road or railway lines should be examined considering all other parameters involved.
 - **Installing restraints** to restrict the failure (toppling) of sensitive equipment and nonstructural components, such as computer equipment, communication devices, batteries, health-care equipment, diesel tanks, or equipment installed on roofs and ceilings.
 - **Improve the redundancy** of specific components where this is cost-effective. For example, redundant diesel generators and diesel tanks in hospitals, main water pumping stations, and strategic buildings.
3. **Readiness and resourcefulness for emergency response**, which is related to the repairs and measures for the safety of the public and the functionality of the critical facilities immediately after the disaster. Particular actions are:
- **Response planning**, including prioritization for restoration interventions, availability of resources (inspection and repair crews) and means (equipment, materials, and spare parts), organization, and coordination of the emergency response. The prioritization for repairs in this phase is related to the emergency needs, such as accessibility and supply of energy to hospitals and critical facilities. Other specific actions that can improve the readiness and rapidity include the arrangements to have helicopters committed for use in post-earthquake inspections of extended networks (e.g., railroads), the regular training of staff, and check and maintenance of material and equipment. The use of advanced tools like GIS and remote sensing techniques and continuous monitoring of the functionality of the networks are nowadays indispensable.
 - The need for **coordinated actions** between the different lifeline owners and stakeholders is also emphasized due to the interactions between different lifeline elements. For example, the restoration of utilities such as gas, water, wastewater pipes, and communication or electric power cables that exist underneath urban roads requires a coordinated action. A representative case of interactions among different lifeline systems during the restoration period is from 1995 Kobe earthquake. The restoration activities of the water and gas networks in the Kobe area have been delayed due to traffic congestion, street blockades, damaged buildings, and water that flowed into gas pipelines. It is clear that an efficient rescue policy and an optimum recovery strategy require the evaluation and the efficient governance of the interactions between different lifeline systems and authorities.
 - Measures to mitigate losses due to **after-shocks**, such as short-term supporting countermeasures of heavily damaged structures.
 - Installation of **early warning systems**, to alert for the coming earthquake and cut off the operation of high-risk facilities such as the gas network or to slow down high-speed trains. Such systems are currently implemented in Bay Area Rapid Transit system (www.bart.gov) and Japan Railways (Nakamura and Saita 2007).

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 4 Effect of mitigation measures and readiness (A, B, C) in the recovery process after the occurrence of a disastrous earthquake and representation of a system with high (R_1) and low (R_2) resilience. Ideally, in case A, the performance of the network can reach the pre-disaster

performance level (P_O) or higher (P_A^*). In case B, the system's performance can reach lower (P_B), P_O , or higher (P_B^*) level, while in case C the performance will most probably reach P_O or lower (P_C) level. The losses are represented by L_A , $L_A + L_B$ and $L_A + L_B + L_C$ for mitigation measures A, B, and C, respectively

4. **Readiness and rapidity for recovery** is related to the restoration period and until the functionality of all lifelines and facilities returns to the pre-disaster level. It can be described in terms of time needed to reorganize services, activities, and functions. An efficient planning is required for the prioritization and organization of restoration works. The post-earthquake restoration approaches are briefly described in a next section. The implementation of pre-earthquake risk reduction measures together with the readiness for recovery considerably affects the evolution of the recovery process (Fig. 4).

The resilience of the system (e.g., water supply, electric power) is defined by its ability to withstand the disastrous event without suffering devastating losses and to recover shortly. The recovery time is the period necessary to restore the functionality of the system to a desired level that can operate the

same, close to, or better than the pre-disaster one. Several uncertainties are associated to the recovery time such as the structural restoration time and the business interruption time. It typically depends on the earthquake intensities and on the location of the system with its given resources such as capital, materials, and labor as well as public policies, following the major seismic event (Cimellaro et al. 2010).

Figure 4 illustrates the response and recovery time of a system with lower and higher resilience in relation with the risk reduction and readiness measures. Three cases are described: with risk reduction and readiness measures (A), without risk reduction measures, but with readiness (B), and without any measures (C). Obviously, in reality there are several variations of risk mitigation measures, resilience levels, and recovery time. Ideally, in case A, the performance of the network can reach the pre-disaster

performance level (P_O) or higher (P_A^*). In case B, the system's performance can reach lower (P_B), P_O , or higher (P_B^*) level, while in case C the performance will most probably reach P_O or lower (P_C) level. Losses are represented by L_A , $L_A + L_B$, and $L_A + L_B + L_C$ for mitigation measures A, B, and C, respectively. Both losses and recovery time are increasing from A to C.

Prioritization for Mitigation Actions

Pre-seismic (retrofitting and strengthening actions), co-seismic, and post-seismic strategies and policies must be based on advanced approaches that quantify the seismic risk of lifelines and critical facilities considering seismic hazard, vulnerability, and exposure of the networks. The final prioritization criteria combine engineering techniques, economic analysis tools and decision-making, or political aspects. The available engineering techniques for seismic risk assessment and prioritization for mitigation actions are classified in two main groups:

(A) *Screening approaches based on multi-criteria value models.* A rating system is used to assign a score in each attribute of the factors that describe the overall risk of the network component. The scaling values are defined based on expert judgment and the experience of past earthquakes, while weighting factors are commonly used in order to account for the relative contribution of each attribute to the overall risk of the component. This type of models has been mainly developed for buildings and bridges, and the main factors considered are (i) the level of seismicity, usually described by the peak ground acceleration (PGA) value as derived by national provisions or based on site-specific studies required for important structures and infrastructures; (ii) the vulnerability of each element at risk, based on the typology and other geometrical and structural characteristics of the element at risk and soil

characteristics, such as local site conditions and the potential for liquefaction or landslides; and (iii) the importance of the structure, which is evaluated based on its function within the network, the impact to the economy, the interdependencies with other lifelines, the public safety, or its importance for the emergency response. Such models have been proposed for buildings, bridges, as, for example, in the USA by the Federal Highway Administration (FHWA 1995) and in Japan by Kawashima and Unjoh (1990) and for utility networks (Wang et al. 1995; Muhlbauer 1996).

(B) *Advanced risk assessment studies* aiming to the estimation of probable direct and indirect losses (physical, performance, economic, social) due to future earthquakes considering also interactions among different systems. A general layout for the seismic risk assessment of lifelines is outlined in Fig. 4 and is further described in Pitilakis and Argyroudis (2014). Inventory and taxonomy/typology definitions of all elements at risk and systems are the necessary initial steps to describe the elements and networks exposed to seismic risk. The estimation of site-specific seismic ground motion and other geotechnical hazards and the selection estimation of appropriate seismic intensity measures (IM) is the basis of the seismic hazard analysis. Vulnerability is the expected response of an element or a network to a given seismic intensity. It is commonly assessed based on fragility models, which estimate the probability of exceeding certain damage states for given seismic intensity. Fragility functions are adapted with respect to the typological characteristics of each element at risk. An extensive review of available fragility functions and state-of-the-art methods for vulnerability assessment of buildings and lifeline components can be found in Pitilakis et al. (2014a).

The expected damage and loss of the entire network are estimated through appropriate systemic analysis, which takes into account the

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 5 General layout for the seismic risk assessment of lifelines

physical damage and the relations and interactions between the different components and systems (Pitilakis et al. 2014b). The interdependencies among different systems may considerably increase the overall impact. The results, which are commonly provided in terms of performance indicators that describe the network functional losses or the expected economic or socioeconomic losses (Khazai et al. 2014), provide the means for an efficient mitigation or recovery planning. In particular, priorities for retrofitting or adding redundancy of the elements with greater risk can be defined. The level of correlation of damaged components with the network loss performance along with additional indicators and criteria for the characterization of the importance of each component can be used in order to classify the mitigation priorities. Obviously, several sources of uncertainties are inherent in the various definitions, models, tools, and methods for estimation of losses, which make the risk assessment of lifelines a complex and challenging topic (Fig. 5).

Post-earthquake Restoration Modeling of Lifeline Systems

Technically the restoration process is part of the recovery process and commonly is expressed by restoration curves, which define the recovered functionality of a damaged network component (e.g., bridge, water pumping station, or harbor crane) as a function of elapsed time since the earthquake occurrence, which normally is the main event. However in case of very strong earthquakes, the aftershock activity is expected quite high for few or several months, a fact that is seriously affecting most actions in the post-earthquake recovery period. For any system, restoration depends on the characteristics and the damage level of the individual components as well as the network performance and the interactions with other lifelines. In general, the estimation of the required time for recovery is a complicated task and varies significantly between different countries or cities, as it depends on numerous factors.

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 6 Restoration curves for reinforced concrete bridges as a function of number of spans and damage state (Argyroudis 2010)

Restoration process is based on the available construction techniques, local experience and expertise, the regulations and regional politics, the available manpower, material and equipment together with the knowledge of the system, the economic resources, the interactions of individual components and networks, the accessibility of the damaged components, and all these in relation with the intensity, typology, and spatial variability of the damages. Hence it is obvious that restoration curves for lifelines may differ considerably from one country or city to another. Modeling of post-earthquake lifeline restoration can be achieved using experts' opinion, empirical data, theoretical models, or a combination of these. In ATC-25 (ATC 1992), restoration curves are constructed using ATC-13 (ATC 1985) data sources that are based on regression analysis of expert opinion data. These restoration curves were adapted also in HAZUS methodology (FEMA 2003). Examples of empirical approaches include the functions developed for the electric power system in Memphis based on the 1994 Northridge earthquake and ATC-25 data (Shinozuka et al. 1998) or for the water system in

same area, based on data from the 1971 San Fernando earthquake (Chang et al. 1996). Figures 6 and 7 show examples of restoration curves for highway bridges and port facilities based on experts' opinion. In some approaches, resource constraints are accounted for by specifying the number of repairs that can be made in any time period as a function of the personnel available, assuming that all necessary material and expertise are available. In this way, the progress of the restoration across time and space is depicted, while it is possible to investigate the effect of prioritization of repairs. This approach has been employed by Isumi and Shibuya (1985), Ballantyne (1990), Chang et al. (1999), and HAZUS (EMA 2003) for water supply system. The personnel and rate of repairs are assumed to be constant or not with time. However, the actual restoration time of each component may be very different depending on the parameters influencing the restoration process. Moreover, the recovery of the whole system is an even more complicated issue as it depends on the restoration of all individual components. Therefore, the aforementioned models are deterministic and

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 7 Restoration curves for cargo handling equipment (Kakderi 2011)

generally of moderate reliability, as the various uncertainties related with the restoration time are not accounted.

Dynamic simulation approaches that can be either deterministic or stochastic have been employed recently to represent utility company's decision variables (e.g., repair prioritization plans, mutual aid agreements, repair resources) and to produce spatially disaggregated restoration curves, so as one can end up with restoration curves for each region of the service area, rather than just one for the entire lifeline system (Kozin and Zhou 1991; Zhang 1992). Statistical variability and uncertainties associated with key parameters, such as post-earthquake damage inspection durations, repair durations for each damaged component, time needed to replace components that cannot be repaired, and amount of available resources, are taken into account by defining these parameters as random variables with specified probability distributions (Nojima and Kameda 1992; Cagnan and Davidson 2007). However, these approaches require several simplifying assumptions and numerous input data, which are not easily and always available.

As a conclusion, the construction of restoration curves for any component and each lifeline system must be defined by local actors, using basically expert elicitation, considering local conditions and constraints. The reduction of the time delays is actually a political decision of great

importance, where local authorities, government, and lifeline actors have a major role. It is also important to notice that any pre-earthquake actions (upgrading, retrofitting of the most vulnerable elements and sectors) have a very beneficial impact on the definition of the specific restoration curves.

Example of Prioritization in the Restoration Process

An example of seismic risk assessment and prioritization for restoration of damages is presented for the port of Thessaloniki in Greece. In this application, the port facilities are classified into main, important, and secondary through appropriate ranking of the value of the exposed elements, based on various factors that describe the role of each element in the system. In that way, the "global value" of each element at risk depends not only on its direct specific value or content (physical and human) but also upon its indirect/immaterial value that is represented by the usefulness and relative role in the whole urban system, at a specific time. Three periods are identified in respect to the occurrence of an earthquake event: normal, crisis, and recovery. "Global value" evaluation in different periods could be a powerful tool for the prioritization of pre-earthquake actions and quantification of the

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 8 Classification of the importance of cargo handling equipment of Thessaloniki's port during the crisis period

overall importance of different complex and coupled lifeline systems. Several criteria for this are used, such as operational attributes, land use, population influenced, human losses, economic and social weight under normal, crisis and recovery circumstances, identity/radiance, environmental impact, and others. Appropriate qualitative or quantitative indicators can then be defined for each period, while relevant measuring units are used for their evaluation and the identification of “main,” “important,” and “secondary” elements and system’s weak points (RISK-UE project: Mouroux and Le Brun 2006; Pitilakis et al. 2010).

The cargo handling equipment of Thessaloniki’s port are classified based on indicators that describe the capacity, location, type of cargo handled, and redundancy (Pitilakis et al. 2010), and representative maps illustrating the classification of elements at risk are constructed (Fig. 8).

Combining “global value” evaluation and vulnerability assessment and using, if necessary, an “expert opinion,” it is possible to estimate priorities and to account for the economic and social losses, for a specific utility system and a given seismic scenario. Recovery activities

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Table 1 Risk analysis matrix showing cargo handling equipment seismic retrofit priorities

Urban risk/ seismic hazard	Priorities		
	Main	Important	Secondary
Complete/ extensive damages	1st priority	1st priority	2nd priority
Moderate damages	1st priority	2nd priority	3rd priority
Slight/minor damages	1st priority	2nd priority	4th priority

could also follow these priorities aiming at efficient seismic risk management procedures. Table 1 summarizes the application of the proposed approach for the cargo handling equipment of Thessaloniki’s port. Figure 10 illustrates the restoration priorities for a damage scenario with mean return period of 475 years (Fig. 9) (Pitilakis et al. 2010).

Restoration curves have been defined in collaboration with the port authority (Fig. 7), based on available manpower, capabilities, local experience, and expertise. Figure 11 illustrates the functionality level of cargo handling equipment at 3 and 18 months after the seismic event,

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 9 Distribution of damages to waterfront structures and cargo handling equipment of Thessaloniki's port ($T_m = 475$ years)

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 10 Restoration priorities of cargo handling equipment of Thessaloniki's port during the crisis period

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Fig. 11 Functionality percentage of cargo handling equipment of Thessaloniki's port in 3 and 18 months' time after the seismic event

Earthquake Risk Mitigation of Lifelines and Critical Facilities, Table 2 Infrastructure upgrades in San Francisco area (Zoback 2014)

Infrastructure provider	Number clients served	Scope of upgrades	Total cost/source of funding
Pacific Gas and Electric	15M throughout North CA	System upgrade of underground gas, electrical components, substations, and administration building	\$2.5B Ratepayers
Bay Area Rapid Transit	400,000 daily ridership	Retrofit core system-aerial structures, stations, trans-bay tube (completion system by 2018, tube by 2023)	\$1.3B Bonds and taxpayers/ \$3 M from FEMA
East Bay Municipal Utility District	1.3M in East Bay	Entire system upgrade: pipelines, fault crossings, dams, administration building, pumping, and treatment plants (completed 1999)	\$0.189B Ratepayers
California Department of Transportation	38.3M statewide	Structurally upgraded and seismically retrofit over 2000 bridges and overpasses, new E span Bay Bridge	\$13.08B CA taxpayers
San Francisco Public Utilities Commission	2.6M residential, commercial, and industrial	Upgrade of >100-year-old Hetch Hetchy water system (pipelines), fault crossings treatment facilities, and reservoirs (completion by 2016)	\$4.6B Bond measure
Total investment			\$21.6B

assuming that the restoration process starts immediately after the earthquake and that there are two available working groups for the restoration process.

Lifeline Seismic Retrofitting Programs

Some examples of risk reduction measures through retrofitting programs taken by lifeline stakeholders over recent years to reduce the impact of earthquakes are given in the following.

Lifelines Council in San Francisco

The city and county of San Francisco convene a Lifelines Council with a scope focused on coordinated risk reduction strategies and post-disaster reconstruction and recovery. The Lifelines Council seeks to develop and improve collaboration in the city and across the region; understand intersystem dependencies to enhance planning, restoration, and reconstruction; share information about recovery plans, projects, and priorities; and establish coordination processes for lifeline restoration and recovery following a major disaster event (<http://sfgsa.org/index.aspx?page=4964>).

In the 25 years since Loma Prieta, San Francisco Bay area infrastructure providers have

dramatically increased their disaster resilience through substantial system upgrades, an investment of \$21 billion funded almost exclusively by ratepayers and taxpayers – almost \$1 billion/year (see Table 2). A five-step strategy has been employed by the main infrastructure providers to increase their earthquake resilience (Zoback 2014):

1. Assess vulnerabilities of their systems to expected earthquakes.
2. Set performance goals for the systems after the earthquake.
3. Communicate risks/benefits and secure funding.
4. Develop creative and innovative solutions for these complex problems. These include building redundancy into the system at the start and taking advantage of, and in some cases funding, research to improve solutions.
5. Continue to reassess system performance as upgrades proceed. Develop real-time damage assessment capability using near real-time maps of earthquake shaking intensity provided by the USGS overlain by their system fragility functions.

Bridges in California

After the 1971 Sylmar earthquake that struck the Los Angeles area and damaged several bridges,

the California Department of Transportation (Caltrans) initiated a bridge seismic safety retrofit program focused on bridge expansion joints. The mid-span hinge and support joint retrofit program was completed in 1989 at a cost of \$55 million. With the significant loss of life and closure of major routes during the 1989 Loma Prieta earthquake, the Caltrans established a new seismic retrofit program for the more than 12,000 bridges in the California State Highway system. This program is focused on identifying and retrofitting existing bridges statewide, bringing them up to the latest seismic safety retrofit standards established to prevent collapse during future earthquakes. In particular, after the Loma Prieta earthquake, the Department initially identified 1,039 state highway bridges (mostly single-column bridges) in need of being retrofitted to meet seismic safety standards (Phase 1 Program). After the 1994 Northridge earthquake, the Caltrans identified another 1,155 state-owned bridges (mostly multicolumn bridges) in need of being retrofitted (Phase 2 Program). The state's bridge earthquake strengthening program, which has been almost completed, involves more than 2,200 structures and costs more than \$12 billion. A separate program was established for toll bridges which are the largest and most complicated bridges in the State. An estimated \$2.6 billion is allocated for this program, which also includes the replacement of the east span of the San Francisco-Oakland Bay Bridge (<http://www.dot.ca.gov/hq/paffairs/about/retrofit.htm>).

Bay Area Rapid Transit (BART) System

BART is one of the Bay Area's most vital transportation links, carrying about 360,000 travelers every day. BART's success in maintaining continuous service directly after the 1989 Loma Prieta earthquake reconfirmed the system's importance as transportation "lifeline." However, because of the likelihood that BART will be subject to a major future earthquake, an Earthquake Safety Program has been recently initiated. The program will upgrade vulnerable portions of the original system to ensure safety for the public and BART employees. Portions of the original system with the highest traffic will be upgraded

not only for life safety but also to ensure that they can return to operation shortly after a major earthquake. The upgrades will be accomplished by using the latest seismic standards to improve the structural integrity of BART facilities. The completion of all earthquake upgrades is anticipated by 2018. The total project is \$1.2 billion (in 2004 dollars). Preliminary upgrade concepts include: Vibro replacement to compact soil backfill, increasing seismic joint capacity and sealing around joints, and new concrete shear walls in the Oakland Ventilation Structure. Potential upgrading concepts for elevated structures include enlarged or reinforced concrete foundations, "jackets" around concrete columns, additional shear keys, and additional foundation piles where poor soil conditions exist (<http://www.bart.gov/about/projects/eqs>).

Lifelines in New Zealand

Lifeline vulnerability to natural hazards including earthquakes had been given prominence in a comprehensive project undertaken by the Christchurch Engineering Lifelines Group in the first half of the 1990s. Utility networks were described, broken down to component level, with each one assessed for vulnerability to the various natural hazards. Assessments considered "importance" to the network as well as "vulnerability" and "damage impact" estimated in three time frames: immediately after the event, period following, and time for return to normality. Different lifeline systems were covered, namely, energy, telecommunications, transport, and water/sewerage. The project also included emergency buildings like broadcasting, police and fire stations, and ambulance bases. Several mitigation measures have been undertaken in the following years. For example, in the water system restraint actions taken for spare parts and equipment, seismic strengthening of reservoirs and pumping stations, valve shut off improvements; in the electric power network, insecure buildings were removed and the control room was relocated, while major transformers and other essential equipment as well as bridge approaches were strengthened to protect cables. In transportation networks, improvements were made at bridges including

Earthquake Risk Mitigation of Lifelines and Critical Facilities,

Fig. 12 Superposition of cost curves as a function of the system performance for seismic retrofit cost, expected damage cost, and total cost

E

strengthening connections between superstructures and substructures, increasing column strength and ductility, strengthening or renewing retaining and approach structures, and strengthening lateral/longitudinal restraint mechanisms. Planning was improved in relation to key roads, bridges, and the important Lyttelton Tunnel. Improvements were made at the airport and port. Additional equipment, such as generators and portable pumps, were also purchased.

The substantial program of seismic mitigation undertaken by Christchurch lifeline utilities has served Christchurch in reducing losses and facilitating emergency responses and recovery during the 2010 (M7.1) and 2011 (M6.3) earthquakes. The damage would have been greater and the response slower if the emergency planning and other preparatory work had not been undertaken.

For example, the electricity distribution seismic strengthening program, commenced in 1996 and progressed systematically each year, costs \$6 million and is estimated to have saved \$60–\$65 million in direct asset replacement costs and repairs. Total repair costs from the 2011 earthquake amounted to only \$150,000. Seventeen bridges in Canterbury, including many in or near Christchurch, were identified as at risk and had been retrofitted at a cost of \$2 million. These measures prevented critical damage, as only one bridge was closed due to approach settlement and

reopened within a day. Similar cases have been noted for other networks and components in the area. It is a representative example of worthwhile investment, as the costs of seismic risk mitigation in Christchurch would have been repaid many times over if these measures were not have been taken place (Fenwick 2012).

Europe

In European countries with high seismicity (i.e., Italy, Greece, Turkey), risk assessment programs have been undertaken in the last decade for public buildings (i.e., hospitals, schools) and upgrades have been implemented in some cases. For other infrastructures (e.g., bridges), risk assessment studies and screening approaches have been partially conducted; however, retrofitting is rather limited. A short overview of the activity of bridge upgrading currently ongoing in Italy is given by Pinto and Franchin (2010).

Economic Efficiency of Seismic Retrofitting Measures

The economic efficiency of seismic retrofitting measures is related to benefit-cost analysis. Figure 12 shows an idealization of economic efficiency based on the concept of performance levels of the system under consideration. The cost

of retrofitting measures is increasing when higher performance levels are desired. On the other hand, the cost of the expected seismic damages, when the retrofitting measures are applied, is decreasing. The total cost (initial construction cost, without considering depreciation and retrofitting cost) is lower in the intersection of the two curves. In order to determine the economic efficiency, both the repair costs after expected earthquakes of different intensities and return periods and the costs of retrofitting measures to achieve certain performance levels have to be considered, usually as a function of the initial construction costs.

Benefit-cost analysis is a well-established tool to assess the viability of seismic risk reduction projects and policies. In particular, the appraisal of earthquake mitigation projects is crucial in making community, policy- and decision-makers, and insurance and construction industry to understand and quantify the effects of earthquake mitigation. The analysis for the economic feasibility of seismic retrofitting considers the achievable loss reduction, investment return period, and retrofit cost. Overall, the organization of mitigation policies for lifelines is a political and economic decision and surely not a decision that is based on emotion or public feeling, which, however, should be seriously considered. The selection of the acceptable risk considering appropriate seismic scenario or scenarios is always a major decision to make. It should take into account and combine different parameters like the detail of the seismic hazard, the will of central and local actors, the available funds, and the financial and technical capability of the community and the country. Epistemic and physical uncertainties are involved in every step of any earthquake risk reduction policy and should be taken into account.

The increase in safety and reliability of lifelines and the reduction of direct and indirect losses against future earthquakes are the main benefits of efficient retrofitting programs. However, they are not the only ones. Retrofitting strategies followed by investment policies are also a serious and efficient tool for short- and long-term growth of economic development, increasing

employment and properties' value, with benefits to the insurance and construction industry.

Summary

Lifelines and critical facilities are essential public infrastructures and networks that support citizen's life, economy, and industry. Experience from past earthquakes reveals that their components are quite vulnerable and the induced damages can have high impact in the emergency response as well as serious economic and health consequences. Losses can be even higher because of the extensive interdependencies between utility networks and infrastructures. Therefore, high priority should be given to secure safety of lifeline facilities against earthquakes and reduce the overall impact.

The decision for mitigation of lifelines against seismic hazard is a quite complex issue as different institutions from public and private sector are involved: governmental and local authorities, lifeline companies, industries, and insurances. Moreover, the decision by itself is very difficult because it should be made based on the results of the seismic risk assessment of lifelines which includes various uncertainties owing to seismic hazard vulnerability, performance, and loss estimation procedures. The risk assessment is the fundamental step for the prioritization of mitigation measures, which in general include the following actions: risk reduction, readiness for emergency response, and readiness for recovery. Risk reduction is related to the strengthening and upgrade of vulnerable assets, improvement of design and construction practices, relocation of components, improvement of redundancy, and security of sensitive nonstructural equipment. Readiness and resourcefulness for emergency response is related to the repairs and measures for the safety of the public and the functionality of the critical facilities immediately after the disaster. Typical measures include installation of early warning systems, advanced response planning, coordinated actions between different entities/stakeholders, and measures to reduce losses due to aftershocks. Readiness and rapidity

for recovery is related to the restoration period and until the functionality of all lifelines and facilities returns to the pre-disaster level. The implementation of pre-earthquake risk reduction measures together with the readiness for recovery considerably affects the evolution of the recovery process.

Pre-seismic (retrofitting and strengthening actions), co-seismic, and post-seismic strategies and policies must be based on advanced approaches that quantify the seismic risk of lifelines and critical facilities considering seismic hazard, vulnerability, and exposure of the networks. The final prioritization criteria should combine engineering techniques, economic analysis, and decision-making tools.

Introduction

Earthquake swarms are a specific type of seismicity. They are generally defined as sequences of seismic events closely clustered in space and time, without a single outstanding earthquake (Mogi 1963). Globally, most seismic energy is released in ordinary earthquakes, represented by a single strong event succeeded by a series of smaller aftershocks (in some cases also preceded by foreshocks) with magnitudes of one or more magnitude units lower than that of the main event. These are so-called mainshock-aftershock sequences. In contrast, an earthquake swarm consists of numerous, mostly shallow, earthquakes, which are missing a single large event. They produce few dominant earthquakes of similar magnitudes so that smaller events are not associated with any identifiable mainshock. Earthquake swarms distinctively cluster in time and space and last from several hours to several months, with some exceptional cases lasting more than a year. Swarms originate in the crust from local stresses generated by volcanic or tectonic activity. In

many cases, there is an overlapping signature of both volcanic and tectonic causes (Scholz 2002). The term “earthquake swarm” (“Schwarmbeben” in German) was very likely first used in the 1870s to describe this peculiar seismicity that occurred repeatedly in W-Bohemia/Vogtland (border of the Czech Republic, Saxony, and Bavaria).

Occurrence of Earthquake Swarms in the World

Earthquake swarms occur worldwide at boundaries of the lithospheric plates (interplate), within the plates (intraplate), as well as in subduction zones, and they are very often related to volcanic areas, areas with high activity of crustal fluids (particularly geothermal fields), and ocean ridges. Additionally, earthquake swarms are also observed in relation to human-induced stress and pressure perturbations like fluid-injection into deep boreholes for purposes of the geothermal energy exploitation. Quite frequent earthquake swarms occur in the Yellowstone volcanic field, which is one of the most seismically active areas of the western U.S. Further examples of “volcanic” swarms include the Hawaiian Islands, Alaska, Japan, New Zealand, and Canary Islands.

The strongest events of earthquake swarms are usually of local magnitudes $M_L < 5$, with few reaching $M_L \approx 6.0$. An extraordinarily strong earthquake swarm with $M_{w_{\max}} = 6.4$ and many $M_w > 5.0$ earthquakes accompanied the volcanic eruption on Miyakejima in Japan, in 2000 (Minson et al. 2007). The earthquake swarm with magnitudes reaching $M_w = 6.2$ has been reported in southern Chile in 2007. The 1965–1967 Matsushiro earthquake swarm in southwest Honshu (central Japan) was one of the most energetic swarms in the world (Cappa et al. 2009). A series of more than 700,000 events (about 60,000 earthquakes were felt) with the largest earthquake of magnitude $M_w = 5.4$ produced ground surface deformations and cracking of the topsoil and enhanced spring outflows, with changes in chemical composition and carbon dioxide degassing.

The most intense interplate earthquake swarms in Europe occur in Iceland, which lies directly on

the mid-Atlantic ridge, which separates Iceland over the two major lithosphere plates, the Eurasian plate to the east and the North American plate to the west. An exceptionally intense earthquake swarm has accompanied the Bárðarbunga volcanic eruption. The seismic crisis started in August 2014 and has been going on for 8 months. The largest earthquake reached magnitude $M_w = 5.6$ and more than 70 events had magnitudes $M_w \geq 5.0$. Further examples of European earthquake swarm areas somehow connected with the plate or microplate boundaries are western Alps, a few areas in Apennines, and also a few areas in Greece. A swarm-like activity preceded a severe $M_w = 6.3$ earthquake in L'Aquila (Abruzzo region, central Italy) in 2009.

Intraplate earthquake swarms occur mainly in Quaternary volcanism areas, which are often characterized by geodynamic unrest and other phenomena like diffuse degassing, geothermal anomalies, and chemical or dissolution anomalies.

A typical European intraplate swarm area is W-Bohemia/Vogtland. Other intraplate earthquake swarm areas affected by Quaternary volcanism are, for example, the French Massif Central, Colorado, and Long Valley in California. Vidale and Shearer (2006) examined earthquake bursts in southern California between 1984 and 2002 and identified 18 sequences as swarm like. An example of intraplate earthquake swarm areas where Quaternary volcanism is missing is the Vosges in France. One of the most intensive nonvolcanic earthquake swarm area in Japan is located in the Wakayama district in southwest Japan. The Wakayama swarm activity was initiated more than 40 years ago and has continued to the present day; the occurrence rate of earthquakes with magnitudes greater than 3.0 is >10 events per year. Earthquake swarms of magmatic origin occur frequently at mid-oceanic spreading centers, which is discussed in more detail in section “[Earthquake Swarms Induced by Magmatic and Volcanic Activity](#).”

Primary Earthquake Swarm Models

Earthquake swarms are of diverse nature; they are usually considered to be of two types: volcanic

and tectonic. Accordingly, several models have been proposed to explain the conditions and mechanisms leading to the formation of earthquake swarms. Mogi (1963) proposed their origination as consequence of stress concentration in unusually heterogeneous rock and considered magma intrusions to be the likely cause of stress accumulation. Hill (1977) proposed a model for the generation of earthquake swarms in volcanic environments, in which they occur on planes connecting the edges of parallel and offset inflating dikes. The magma intrusion causes dike inflation, which increases the stress difference $\sigma_1 - \sigma_3$ (σ_1 is maximum and σ_3 minimum local stress) and drives slip on the shear planes. Another model based on mechanical coupling between the rupture process and fluid migration was proposed by Yamashita (1999). Here, numerous pores are created due to the rupture and this allows fluids to migrate from the high-pressure compartments into the ruptured zone. Swarm earthquakes are generated if the rate of the pore creation is high, and consequently, the pore volume rapidly increases. Since the pores are not filled with fluids during their creation, fluids flow into the fracture zone causing a pore pressure decrease with time and ceasing the rupture growth. But the consecutive rise of the pore pressure reactivates the rupture process and the swarm activity goes on. In such a case, the seismic b -value (basic parameter of the frequency–magnitude distribution; for more details, see section “[Statistical Characteristics of Swarm Earthquakes](#)”) is unusually large, which corresponds to the high b -values observed in volcanic earthquake swarms. In case the rate of the pore creation is small or there are no new pores at all, the model provides the foreshock-mainshock sequences and small b -values. A prerequisite for Yamashita's model are continuously open faults, which serve for the fluid supply.

Local Networks: A Tool for Understanding Earthquake Swarms

All the models mentioned above imply that earthquake swarms are phenomena which occur in diverse tectonic environments. Their underlying

causes are not easy to disclose. For the same reasons, earthquake swarms are defined rather empirically than deterministically and their triggering mechanisms and driving forces are also unclear. A promising way to get a deeper insight into their driving mechanisms is a detailed analysis of swarm seismicity including the smallest possible events, over a long time period. A prerequisite for this is high-quality data from long-term observations by means of a dense network of local seismic stations providing a sufficiently low completeness magnitude ($M_L < 0$ as an optimum). Among others, similar networks are operating in the W-Bohemia earthquake swarm region (WEBNET consisting of 22 stations), in Iceland (SIL-network of about 70 stations), and in Yellowstone National Park (Yellowstone seismic network consisting of 26 stations).

Statistical Characteristics of Swarm Earthquakes

The Gutenberg–Richter law, $\log N = a - bM$, where N is the number of events having a magnitude $\geq M$ and a and b (b -value) are constants, expresses the relation between earthquake size and the frequency of their occurrence in a particular region and time period, hence it is the most important scaling relationship in the earthquake statistics. The constant b signifies the rate of smaller to larger events. In general b -values for ordinary mainshock–aftershock sequences as well as for seismicity in particular region and given time period typically range from 0.8 to 1.0. The b -value of 1.0 implies that there will be a tenfold increase in the number of events for every unit drop in magnitude. It means that distribution of earthquakes with respect to magnitudes is scale invariant, appears to be self-similar and obeys a power law. Computation of the magnitude–frequency distribution is easy to do but its interpretation may be tricky. Reliable evaluation of b -value requires a complete data set over at least three orders of magnitudes; an incompleteness of the analysed data may result in false b -value.

It is generally assumed and often claimed in literature that b -values of earthquake swarms

typically exceed 1.0 and are often as high as 2.5 (e.g., Lay and Wallace 1995), which implies prevalence of small events against larger ones in individual swarm activities. However, relevant studies show that b -values of both tectonic and volcanic swarm activities vary frequently between common values of 0.7–1.5. The b -values ≈ 0.85 –1.0 are characteristic for intraplate earthquake swarms in W-Bohemia/Vogtland, similar b -values were found for several earthquake swarms on the Reykjanes Peninsula and in the Hengill volcanic complex in SW-Iceland (Fig. 1). Also some volcanic earthquake swarms show b -value < 1.0 , e.g., the earthquake swarm prior to the 1995 eruption of Mt Ruapehu in New Zealand (Hurst and McGinty 1999) having b -values ≈ 0.75 . Note that the b -value close to 1.0 indicate that the earthquake swarm concerned is a mixture of mainshock–aftershock sequences that are largely controlled by a local tectonic stress.

The b -values > 1.0 are also observed quite often, particularly for volcanic swarms. For example, b -values of the Yellowstone earthquake swarms range from 0.6 to 1.5 (Farrel et al. 2009), b -value ≈ 1.2 are typical for swarms in Long Valley Caldera and the adjacent Sierra Nevada (Hill et al. 2003). The $M_{L\max} = 4.6$ earthquake-swarm activity associated with an eruption of El Hierro (Canary Islands) showed b -value ≈ 1.2 , however, the early pre-eruptive activity was characterized by a b -value of 2.25 (Ibáñez et al. 2012). Those b -values > 1.0 occur in nonvolcanic areas such as the Ubaye swarm (French Alps) in 2003–2004, $b = 1.2$ (Jenatton et al. 2007) or the Sampeyre swarm (Western Alps, Italy) in 2010, $b = 1.4$ (Godano et al. 2013). Extremely high b -values of 1.5–2.0 have been indicated for earthquake swarms in circum-Pacific subduction zones (Holtkamp and Brudzinski 2011) and an even higher value of 2.3 was determined by Einarsson (1986) for divergent segments of the Mid-Atlantic Ridge (see also section “Earthquake Swarms Induced by Magmatic and Volcanic Activity”).

For temporal evolution of seismicity at plate boundaries, it holds that the aftershock rate decays with the time from the mainshock,

Earthquake Swarms, Fig. 1 Statistical characteristics of interplate earthquake swarms from three different areas in SW-Iceland: Hengill volcanic complex in 1997, $M_L \leq 4.5$, Ölfus area in 1998, $M_L \leq 5.1$, and Krísuvík area on the Reykjanes Peninsula in 2003, $M_L \leq 4.2$, and of intraplate W-Bohemian earthquake swarms in 2000, $M_L \leq 3.3$ and in 2008, $M_L \leq 3.8$, which were located on the same

fault segment (Fischer et al. 2014). (a) The magnitude–frequency distribution of all these swarms shows b -value between 0.8 and 1.0, which suggests an occurrence of the mainshock–aftershock sequences in these swarms. (b) The interevent-time probability distribution signifies a similarity of the event-rate (rapidity) of the individual swarms

according to the power law $N(t) \propto (t + c)^{-p}$, where t is the time after the mainshock, c is constant, and exponent $p \approx 1$ (modified Omori law). Yet no adequate law was proposed for earthquake swarms. The reason is simply the absence of a single mainshock; alternatively the swarm can be considered as a number of overlapping aftershock sequences in time and space (Fischer et al. 2014). To describe this behavior the epidemic type aftershock sequence model (ETAS) was proposed by Ogata (1988) which considers each earthquake being capable of generating aftershocks and its aftershock productivity increases with its magnitude.

Space and Time Distribution of the Foci

Earthquake swarms frequently originate in the upper part of the Earth's crust. Depths of swarm earthquakes all over the world range approximately between 2 and 20 km, while deeper earthquake swarms exist but rather infrequently. The majority of swarm events are located around 10 km and shallower. For example, earthquake swarms in the Yellowstone volcanic field occur at depths between 2 and 12 km (Farrel et al. 2009),

similar depths are reported for earthquake swarms in continental rifts of the Rio Grande and Kenya (Ibs-von Seht et al. 2008). The hypocenters of the 2000 volcanic Miyakejima swarm in Japan were located in a large range of depths between 5 and 20 km (the strongest $M_w = 6.4$ earthquake occurred at depth of 10 km), while foci of the nonvolcanic Matushiro earthquake swarm of 1965–1967 in central Japan took place from near surface down to about 12 km.

Focal depths of the intraplate earthquake swarms in W-Bohemia/Vogtland vary from 5 to 20 km but those in the main focal zone Nový Kostel, where more than 35,000 $M_L < 4.0$ events were recorded during the last 25 years, range between 6 and 13 km. Interplate earthquake swarms in SW-Iceland – on the Reykjanes Peninsula, ($M_L \leq 4.2$), in the Hengill volcanic complex, ($M_L \leq 4.5$), and Ölfus area ($M_L \leq 5.1$) are a bit shallower compared to those in W-Bohemia/Vogtland (Fig. 2).

Extremely shallow earthquake swarms have been observed in the caldera of Hakone volcano in central Japan, the hypocenters of the 2009 swarm ($M_L \leq 3.2$) were located at depths between 0.5 and 2.8 km (Yukutake et al. 2011). Even shallower was the Tricastin earthquake swarm,

Earthquake Swarms, Fig. 2 Space and time distribution of earthquakes in the W-Bohemian earthquake swarms of 2000 a 2008 and the SW-Icelandic swarms in the Hengill volcanic complex in 1997 and in the K  suv  k

area (Reykjanes Peninsula) in 2003. The spatial distribution of foci for each earthquake swarm is represented by two plots: (*Top*) the map view, and (*Middle*) depth view along the strike. (*Bottom*) The time development of swarm

the Rhône Valley in France, ($M_L < 1.7$), in 2002–2003, that took place at depths from 200 m to 1 km (Thouvenot et al. 2009). A striking phenomenon is meteorologically triggered earthquake swarms at Mt. Hochstaufen in SE-Germany ($M_L \leq 2.4$), with depths from 100 m down to 2.5 km (Kraft et al. 2006).

Earthquake swarms in the lower crust, where ductile deformation is expected, are relatively rare but occasionally observed beneath active volcanoes. An example is the SW-margin of Long Valley Caldera in California (Shelly and Hill 2011), where both shallow brittle-failure swarms at depth down to ≈ 7 km and deep brittle-failures at depths between ≈ 18 and 30 km occurred. Another example is the 2007–2008 swarm beneath Mt. Upptyppingar (a part of the Iceland Northern Volcanic Zone) that was of the magmatic intrusion origin; the focal depths range between 10 and 20 km, see Fig. 3. (It is worthy of notice that this swarm activity was evidenced by a significant deformation, which was observed at permanent GPS stations in the region).

Earthquake swarms, regardless of the tectonic environment, are characterized by a dense clustering of the foci in time and space and in most cases by pronounced migration of the foci. Individual swarms usually initiate abruptly, event rate accelerates and magnitudes of events increase. The event rate may differ from case to case considerably, but quite often exceeds 100 $M_L > 0$ events per hour when swarm activity is culminating. Larger earthquake swarms are commonly comprised of several swarm phases, which are quite often separated by even longer periods of inactivity, during which the swarm activity shifts between different segments of the fault. Large events tend to occur in later swarm phases rather than in the beginning of the swarm.

Spatial clustering and focal migration of swarms are related to each other by their origin. In the beginning of a particular swarm and/or individual swarm phases, the foci cluster tightly in the vicinity of the activity nucleation point and gradually migrate outwards. The extent of the focal migration depends largely on switching the activity among several portions of the fault. Individual swarms show quite different migration patterns, even if they occur in the same place. Two W-Bohemian swarms of 2000 and 2008, which took place on the same fault segment (they represent “swarm twins”), are an informative example of an unusually different earthquake swarm development (Fischer et al. 2014). The former, with maximum magnitude $M_L = 3.3$, was of a distinctly episodic character: most of the events occurred during eight swarm phases with abrupt onsets lasting 2–4 days, which were followed by longer quiescence periods. The swarm activity culminated in the last phase during which all the $M_L > 3.0$ earthquakes occurred. The latter, with maximum magnitude $M_L = 3.8$ showed a much faster seismic-moment release, which resulted in the overlapping of the subsequent swarm phases and thus the 2008 swarm displayed only two distinct phases. Most of the seismic moment, which was more than three times larger than that in 2000, was released during the first 8 days. Both the 2000 and 2008 swarms initiated at the bottom of their focal clusters but they showed different patterns of focal migration (Fig. 2).

The focal-migration rate in earthquake swarms depends on the driving force. In general it differs for individual swarm areas and can be highly variable for a particular swarm. Extremely high migration rates between 0.5 and 1.2 m/s (approximately a common walking speed) are

Earthquake Swarms, Fig. 2 (continued) activity is depicted by the magnitude–time plot. Color coding from dark blue to dark red corresponds to the course of seismicity in time. The north direction is marked by arrow. Note that both W-Bohemia swarms, which happened on the same fault segment, initiated on the bottom of the focal cluster but their migration pattern is different. Further note that the 2003 K  isuv  k swarm began by the strongest

earthquake whereas in the remaining swarms the strongest events occurred during some later swarm phase. The events were localized by applying the double-difference method (HypoDD program package) to data of WEBNET for the West Bohemia swarms and of SIL for Icelandic swarms (section “Local Networks: A Tool for Understanding Earthquake Swarms”)

E

Earthquake Swarms, Fig. 3 A deep earthquake swarm beneath Mt. Upptyppingar, $M_L \leq 2.2$, in 2007–2008 that accompanied magmatic intrusion into a dike in the lower crust of Iceland’s Northern Volcanic Rift Zone (for more detailed information of earthquake swarms induced by magmatic activity see section “[Earthquake Swarms Induced by Magmatic and Volcanic Activity](#)”). The swarm exhibited extremely high b -value of 2.1. The spatial distribution of foci is shown in two depth sections: (a) view along the strike and (b) view across the strike. In (a)

and (b) the coordinate system is rotated 9° counter clockwise, so the easting is along the strike of the focal belt. It is obvious that the swarm is of planar character (the dip of the fault plane is $\approx 40^\circ$). The temporal development of the swarm activity and focal depth changes are depicted in plot (c). The time-axis is scaled in months. It is apparent that during an 11-month period the swarm activity migrated gradually upwards. The events are located by the double-difference method applied to the SIL data

observed in earthquake swarms that are closely connected with intrusion of dikes, such as in the rift zone of Krafla in Iceland or in the Afar rift in Ethiopia (Wright et al. 2012). Massin et al. (2013) reports a fairly high migration rate of 1 km per day for the Yellowstone Lake swarm in 2008–2009. The focal-migration rate of intensive

intraplate swarms amounts to several hundreds of meters per day. The fact that earthquake swarms mostly occur in volcanic or postvolcanic areas, which exhibit high fluid activity in crust, leads to a general assumption that swarming with the seismicity migration are governed by three possible processes: (a) magma migration within the

Earth's crust, (b) dike intrusion propagation (for more details see section “[Earthquake Swarms Induced by Magmatic and Volcanic Activity](#)”), or by (c) pressurized hydrothermal fluids diffusing within permeable fracture zone along the fault. Accordingly, Vidale and Shearer (2006) suggest that the fluid pressure fluctuations or aseismic slip as plausible driving mechanisms of the swarm-like sequences in southern California (section “[Occurrence of Earthquake Swarms in the World](#)”).

Source Mechanisms

Knowledge of source mechanisms is of crucial importance for understanding of rupturing of earthquake swarms and revealing the forces driving the swarm activity. The fact that earthquake swarms mostly occur in volcanic areas, ocean ridges, or in areas with high activity of crustal fluids begs the question of possible differences between forces which bring about and govern rupturing of swarm-like and ordinary earthquakes. The source mechanism is an equivalent of the body forces acting in the point source in an elastic medium, hence it provides the first information about rupturing process on the fault (Dreger, this issue). Its unconstrained mathematical representation is the seismic moment tensor which is in its completeness 9 dipole forces but only 6 of them are independent due to symmetry. The moment tensor is usually decomposed into three force systems (components): double-couple (DC) corresponding to shear slip on a fault, the isotropic (ISO) representing volumetric changes due to explosion or implosion, and compensated linear-vector dipole (CLVD), which has no physical interpretation (for more details see Vavryčuk 1, this issue). For example, the CLVD model may approximately represent an opening of cracks due to the magma injection. But in the CLVD model it is implicitly assumed that material flows rapidly into the opening crack from the nearby area so that no net volume change is involved. However, this flow may not occur very rapidly in viscous magma and on the short timescale (Minson et al. 2007).

Ordinary tectonic earthquakes are mostly shear slips along a fault, i.e., the slip direction is parallel to the fault plane, which is represented by the double-couple (DC) force equivalent, while the non-double-couple components (ISO and CLVD) are insignificant. However, earthquakes where crustal fluids act in the rupturing process need not be pure shear slips along a fault. If the fluid pressure is high enough, it can facilitate the slip by reducing the normal stress on the fault. The pressurized fluids may also cause fracturing by tensile cracks. Rupturing during which the shear slip is coupled with the simultaneous opening of fault results in a slip inclined to the fault plane by the slope angle α (so-called tensile earthquake, for more details see Vavryčuk 2011). Such earthquake is represented by a more complex force equivalent, which is manifested by significant non-DC components (both ISO and CLVD) of the source mechanism (for more information refer to Julian et al., this issue).

The DC component includes information about magnitude of the double-couple forces and focal mechanism (DC constraint of source mechanism). Focal mechanism is represented by three DC angles – strike, dip, and rake – which define geometry of the fault plane and the slip angle along the fault plane. It depends on local stress, i.e., the orientation of the principal stress axes σ_1 (maximum stress), σ_2 (intermediate stress), and σ_3 (minimum stress) relative to the fault plane. There are three basic faulting types: strike-slip (σ_1 and σ_3 are horizontal, σ_2 is vertical), normal (σ_2 and σ_3 are horizontal, σ_1 is vertical) and thrust (σ_1 and σ_2 are horizontal, σ_3 is vertical). Other focal mechanisms, the oblique normal and oblique thrust, are a combination of strike slip with normal and thrust type (for more details see Vavryčuk 2, this issue). In general, all types of focal mechanisms occur in earthquake swarms depending on the tectonic and local-stress conditions in a particular area. Nevertheless, when analyzing earthquake swarms in the world, it appears that oblique normal strike-slip faulting prevails. A characteristic feature of earthquake swarm is fairly significant spatial variation of the focal mechanisms in a particular swarm area as well as during individual swarms; very often each focal

Earthquake Swarms, Fig. 4 Distribution of the earthquake swarms in the main focal area of W-Bohemia/Vogtland and typical source mechanisms in the individual swarms. The section along the strike is depicted on the *right*, the cross-section is on the *left*. It is obvious that the focal area consists of a few shorter faults. All but one source mechanisms are pure shears; the DC angles fit the geometry of the corresponding fault segments. The

mechanism, which is depicted as the second from the left, prevailed in the second phase of the 1997 swarm. It contains significant non-DC components (both ISO and CLVD), the pattern indicates tensile earthquakes. The events are located by the same way as in Fig. 2. The source mechanisms are retrieved in the full moment-tensor description by inversion of amplitudes of the direct P- and S-waves from stations of the WEBNET network

cluster is characterized by its own focal mechanism family (see Fig. 4). It points out a rather complex system of differently oriented shorter faults with stress heterogeneities at small spatial scale, which is very likely one of the prerequisites for the strain-energy release in the form of earthquake swarms.

Existence of tensile swarm earthquakes is still a question at issue. The percentage of the non-DC part in the moment tensor of tensile events is fairly sensitive to the deviation of the slip vector, for example, a deviation of $\alpha = 5^\circ$ out of the fault plane generates up to 20 % of the non-DC components (Fig. 2 of Vavryčuk 2001). However, even large non-DC components can be an artifact of the inconsistency of data, which are inverted for moment tensor. Typically, insufficient distribution of sensors around the focus gives rise to apparently large fictitious non-DC components, particularly of CLVD. Further causes can be inaccurate or noisy data used for the moment-tensor inversion, inaccurate localization of the hypocenter, or a poor seismic-velocity model of the area under study.

The non-DC earthquakes have been identified at a number of hydrothermal and magmatic centers, e.g., in Long Valley Caldera (Foulger et al. 2004) or Hengill volcanic complex in SW-Iceland (Julian et al. 1997), as well as in the intraplate area of W-Bohemia/Vogtland (Horálek et al. 2002). However, there are only few papers dealing with a detailed analysis of non-DC earthquakes in individual earthquake swarm areas or in a particular swarm. So an existence of tensile swarm earthquakes and their possible connection to magma intrusion or to fluid transport is still unclear. This can be demonstrated by the following examples: (1) The Long Valley Caldera, which is still volcanically active and hosts an extensive hydrothermal system. The source mechanisms of swarm events from there were investigated by several teams of authors, however, the results appear ambiguous. For example, Stroujkova and Malin (2002) analyzed the mid-1997 swarm and arrived to the conclusion that majority of the resulting mechanisms appear to be of the DC nature, while Foulger et al. (2004) reported the occurrence of significantly non-DC

source mechanisms, inconsistent with simple shear faulting, for selected events of this swarm. Afterwards, Templeton and Dreger (2006) showed that fluid-influenced earthquakes are quite rare in the Long Valley volcanic region and that majority of local earthquakes are best characterized by a simple DC source model. (2) W-Bohemia/Vogtland, a European intraplate area with extinct Quaternary volcanism manifests present geodynamic unrest by persistent swarm seismicity and degassing of big amount of CO₂ (of about 500 m³ per hour) of the upper-mantle origin. The moment tensors of earthquake swarms in the 1997, 2000 and 2008 events signify fairly different amounts of non-DC components of respective source mechanisms. It appears that swarm earthquakes, which occurred on the optimally oriented faults relative to the local tectonic stress, are pure shears. It is the case of both 2000 and 2008 swarms in which the faulting was governed merely by local tectonic stress (Horálek and Šílený 2013). A question is the 1997 swarm in which two types of source mechanisms occurred (Horálek et al. 2002): pure shears in the first swarm phase but significantly non-DC mechanisms in the second swarm phase (thrust-mechanism type colored dark blue in Fig. 4), which may indicate the occurrence of tensile earthquakes on a less favorably oriented fault segment. However, one cannot rule out that the non-DC components are due to the small number of stations which were used in the moment-tensor inversion of the 1997-events. (3) Minson et al. (2007) tried to find non-double-couple mechanisms of selected earthquakes in a strong Miyakejima volcanic swarm in Japan during the year 2000 and concluded that the source mechanisms of the most analyzed earthquakes appear to be related to inflation of the dike yet their source mechanism solutions are ambiguous.

Possible Triggering Mechanisms and Driving Forces

As far as the mainshock-aftershock sequences at plate boundaries are concerned, there is a general understanding that the main shock is triggered by

plate motion loading and aftershocks are a result of stress redistribution due to the main shock. Yet there is no common knowledge how it works in the case of earthquake swarms. In the case of earthquake swarms it appears useful to distinguish the triggering mechanisms that lead to the initiation of the activity and driving forces that keep the activity running.

Compared to tectonic earthquakes at the plate boundaries, the intraplate earthquake swarm areas miss the plate motion that could periodically bring the fault to failure. Recent studies have tried to understand the possible triggering mechanisms by probing/imaging anomalous crustal structures within seismic swarms linked to fluids (e.g., Lin and Shearer 2009; Kato et al. 2010). It is assumed that a fluid overpressure builds up and acts as a triggering mechanism of earthquake swarms. The subsequent swarm activity is then probably driven both by the fluid flow along the fault zone and stress transfer from previous earthquakes. This idea is based on characteristic features of earthquake swarms that help us to disclose their background mechanisms.

One of the most striking features of earthquake swarms is their focal migration, which is often attributed to the fluid flow along a quasipermeable fault zone. The most frequent model of this driving force is based on diffusive propagation of the pore-pressure front from a fluid source within a poroelastic medium defined in a simplified way by the formula $r = \sqrt{4\pi Dt}$ (Shapiro et al. 1997). Here, r and t are the distance and time interval of the foci from the first event, which corresponds to the source of fluids, and D is the hydraulic diffusivity. A different fluid-related model employs the preferential upwards migration of the hypocenters, which is attributed to the buoyancy of fluids that results in hydraulic fracturing of the rock. This allows for estimation of overpressure responsible for the swarm triggering which Hainzl et al. (2012) obtained an overpressure of 20 MPa for the W-Bohemian swarm in 2008. Daniel et al. (2011) analyzed the effective stress necessary to drive the 2003 swarm in Ubaye, France, and obtained a maximum excess pore pressure of 8 MPa.

Clustering of earthquakes in space and time (see Fig. 2) cannot be explained by fluid flows that appear too slow to be responsible for fast earthquake interactions over the first seconds and distances of hundreds of meters. That is why a similar mechanism that drives aftershock series, the static and dynamic Coulomb stress change due to previous earthquakes, is considered. The point is that the stress released within the rupture area of an earthquake brings about the stress increase in some areas outside the rupture. This results in loading of the adjacent ruptures and their subsequent rupturing. A similar mechanism was considered for example by Hainzl (2004) who used numerical simulation based on fluid diffusion and stress transfer for modeling the activity of the 2000 swarm in W-Bohemia. He found that while the hypocenter spreading is explainable by fluid diffusion, coseismic and postseismic stress transfer is necessary to explain the temporal clustering. Fast stress interactions between consecutive earthquakes, which prevailed in the direction of seismic slip are also documented by Fischer and Horálek (2005).

The repeated loading of the fault plane by successive pressure increase is illustrated in Fig. 5. Here the effective stress decreases due to fluid pressure increase until the shear stress exceeds the failure envelope, which results in shearing and decrease of the differential stress represented by the diameter of the Mohr circle. Further increase of pore pressure leads to repeated failure.

Earthquake Swarms Induced by Magmatic and Volcanic Activity

A general relationship between swarm activity and volcanic regions has been recognized for a long time, but yet, the causal relationship has not been clear, i.e., whether magmatic injection is a direct driving force of the swarm or whether the strain release in an earthquake swarm is governed by the inhomogeneous crustal structure and stress field (possibly influenced by pressurized hydrothermal fluids) in a given region. Recent case histories from Iceland revealed that earthquake

Earthquake Swarms, Fig. 5 Mohr–Coulomb diagram illustrating the reactivation of earthquake slip due to increase of the pore pressure Δp . The failure envelope, which is indicated by the inclined line, shows the failure shear stress $\tau_f = \mu(\sigma_n - p)$, where μ is the friction coefficient. The increasing pore pressure results in decrease of the effective stress ($\sigma_n - p$), this way reaching the failure strength. Shear stress is released by the seismic slip, which is expressed by decreasing the stress difference corresponding to the diameter $\sigma_1 - \sigma_3$ of the Mohr circle

swarms, which are directly a consequence of magmatic intrusion into the crust, are accompanied by more extensive strain (both in magnitude and spatial extent) than earthquakes that are caused by fracturing in a crustal stress field (Pedersen et al. 2007). The ratio of total seismic moment of the swarm earthquakes to the volumetric moment of the episode, measured geodetically, is a sensitive parameter that distinguishes between the swarm induced tectonically and that caused by a magmatic intrusion and volume change. A distinction can be made between at least three types of intrusive activity leading to swarm-like earthquake activities:

1. Inflation of a crustal magma chamber. A preexisting molten batch of magma will inflate if injected by fresh magma. The increasing pressure sets up a stress field in the surrounding crust that will eventually lead to fracturing and earthquakes, mainly in the volume above the chamber. The rate of the seismic moment release is governed by the rate of flow into the chamber. This behavior has been documented for the inflation periods of the Krafla volcano in 1975–1988; the Grímsvötn volcano in 1983, 1998, 2004, and 2011; and the Hrómundartindur volcanic

system in 1994–1998, in Iceland (e.g., Pederesen et al. 2007, and references therein). These periods may last for days, to months, to even a few years. The largest swarm earthquakes may be between magnitude $M = 4$ and 5.

2. Intrusion of dikes or sills into the crust. If increasing magma pressure fractures the surrounding crust a dike propagates away from the magma source. The dike tip changes the local stress and thus induces fracturing and earthquakes. The rate of propagation depends on the regional stress, the width of the dike, and viscosity of the magma. Large variation in the waveforms is one of the characteristics of earthquake swarms of this origin, especially if the fracture front approaches the surface. Propagating swarms of this type have been documented in the Afar rift in Ethiopia (Wright et al. 2012), in the rift zone of Krafla, and Bárðarbunga volcanic system in Iceland, where an intense seismic crisis has accompanied the large lava eruption that began in August 2014 (Sigmundsson et al. 2015). In all these cases the dikes are vertical and propagate horizontally away from the magma source. Sill propagation accompanied by earthquakes preceded the eruptions of Eyjafjallajökull in 2010.
3. Extrusion of lava domes at volcanoes, and its subsurface equivalent, the intrusion of cryptodomes, is frequently accompanied by earthquakes. Domes may have steady or episodic growth, with emplacement times ranging from a few hours to many decades. The accompanying earthquakes therefore show a swarm-like behavior on various time scales. They typically have the characteristics of B-type volcanic earthquakes (Chouet 1996), which have indistinct P-waves, weak or no S-waves, and a low-frequency coda.

Several cases are known of earthquake swarm activity accompanying caldera collapses. The latest case is that of the slow collapse of the Bárðarbunga caldera in 2014–2015 following dike propagation and a large lava eruption. More than 70 $M \geq 5.0$ earthquakes occurred on

the caldera fault in response to more than 60 m of caldera subsidence.

Ever since the discovery of mid-oceanic plate boundaries, it has been recognized that there is a fundamental difference between the seismic activity of transform boundaries and that of divergent boundaries, i.e., spreading centers. The transform-zone seismicity is characterized by mainshock-aftershock earthquake sequences having b -values of 0.8–1.0 and strike-slip faulting mechanisms, with maximum magnitudes $M \approx 6.5$ –7.0. The spreading-center earthquakes tend to occur in swarms, fault plane solutions show normal faulting, b -values are high, as high as 2.3, and the largest earthquakes rarely exceed magnitude $M = 6.0$ (e.g., Einarsson 1986).

The association here with an area of volcanic activity is obvious, but even with all of these mentioned studies the causal relationship is still debated. Experience from divergent boundaries on land, in Iceland and East Africa, appears to indicate that both explanations apply. Dike intrusions associated with rifting do produce earthquake swarms (Wright et al. 2012), but swarms that do not seem to be associated with magmatic activity are also common.

Conclusions

Earthquake swarms represent a specific type of seismicity without a mainshock, usually with a gradual increase of seismic activity, clustering in time and space, and migration of their hypocenters. In contrast to mainshock-aftershock sequences, earthquake swarms occur in various tectonic environments including both purely volcanic areas and areas with no active volcanism. Their recognition is still in progress and thanks to more detailed observations it turns out that they are more common than thought before. Their diverse behavior is expressed in multiple models suggesting their origin. Besides the models based on fluid injection and migration along faults, recent hypotheses suggest aseismic loading by creeping faults. Some recent observations show that earthquake swarms can share the same faults

with other types of seismicity. In terms of the wide range of their behavior it appears possible that volcanic swarms and mainshock-aftershock sequences represent end members of a continuous variety of seismic activity that is governed by a combination of two basic types of external loading: fluid injections on one end and tectonic loading on the other end.

Summary

Earthquake swarms are sequences of numerous events closely clustered in space and time and do not have a single dominant mainshock. A few of the largest events in a swarm reach similar magnitudes and usually occur throughout the course of the earthquake sequence. These attributes differentiate earthquake swarms from ordinary mainshock-aftershock sequences. Earthquake swarms occur worldwide, in diverse geological units. The swarms typically accompany volcanic activity at margins of the tectonic plate but also occur in intracontinental areas where strain from tectonic-plate movement is small, but large heterogeneities of stress and fault strength may exist. It implies that earthquake swarms generally originate from volcanic and tectonic episodes. The swarm earthquakes are usually of magnitudes $M < 5$, with some exceptional events reaching or exceeding $M \approx 6.0$. The b -value of the frequency–magnitude distribution $\log N = a - bM$ of both tectonic and volcanic swarms varies mostly between 0.7 and 1.5 but many earthquake swarms show $b \approx 1$ which is a typical b -value for mainshock-aftershock sequences. Depths of swarm earthquakes range approximately between 2 and 20 km with the majority of swarm events located around 10 km and shallower. Deeper earthquake swarms also exist but rarely occur. Earthquake swarms exhibit usually pronounced migration of the foci, particularly the swarms that are closely connected with intrusion of dikes. The source mechanisms, which are an equivalent of the body forces acting in the point-source approximation, signify that the swarm earthquakes are

mostly shear-slips along a fault just as ordinary tectonic earthquakes. In special cases of magma- or fluid-influenced earthquakes, more complex tensile rupturing might occur. However, the existence of tensile swarm earthquakes and their possible connection to movements of magma or fluids is still an open question. Also, triggering mechanisms and driving forces of earthquake swarms remain unclear. These mechanisms are mainly related to activity of pressurized hydrothermal fluids, magma injection, or dike intrusion, and also to aseismic loading by creeping faults. Accordingly, numerous models trying to explain the seismic-energy release in the form of earthquake swarms have been proposed.

Acknowledgments We are grateful to both anonymous reviewers for their valuable suggestions, which helped us to improve the paper substantially. Most of the work was accomplished within the Grant Project P210–12–2336 of the Grant Agency of the Czech Republic “Earthquake swarms and their triggering mechanisms and driving forces in diverse tectonic environments (Bohemian Massif, Mid-Atlantic ridge, French Alps).”

Earthquakes and Their Socio-economic Consequences

Introduction

One does not have to go far back in time to be reminded of the great force of Mother Nature and the havoc an earthquake can cause in terms of direct damage to the natural and built environment (Bam Earthquake in 2003, Kashmir Earthquake in 2005, Wenchuan Earthquake in 2008, Haiti Earthquake in 2010, Great East Japan Earthquake and Tsunami in 2011, Kobe Earthquake in 1995). Over the past decade, earthquakes have become costlier, both in terms of social and economic costs. Figure 1 shows a graph of earthquake fatalities. Even allowing for population growth during that period, of around 2 % per annum globally, it would be difficult say it is reducing. The current decade is the worst in the last 50 years.

In this chapter we shall first examine what are the socio-economic consequences of earthquake and then discuss briefly how socio-economic consequences are recorded and the difficulties in collecting and highlight the discrepancies in these data. This will be followed by a review of recent efforts to standardize the definitions of social and economic parameters. The causes and the contributing factors to differences in socio-economic consequences are also explored in section “[Characteristics of Socio-economic Consequences](#).” An assessment of the socio-economic

Earthquakes and Their Socio-economic Consequences,

Fig. 1 Earthquake fatalities as a function of earthquake magnitude. Post-2,000 events are named (Adapted from Bilham and Hough 2006)

consequences of two case studies, the L'Aquila earthquake of 2009 in Italy and the more recent Great East Japan earthquake and tsunami of 2011, will be examined in detail in section “Two Events in the Twenty-First Century.” The main objective of this section is to not only compare and contrast these events but also to draw important conclusions on the factors affecting recovery and therefore long-term socio-economic impacts on societies affected by earthquakes. The intention is to draw this chapter to a close by looking to the future and examining what as a community of seismologists, engineers, social scientist, public health practitioners, economists, and politicians can be done to eliminate the prospect of a million-death earthquake (Musson 2012)?

Since 2000, more than 1,000,000 people have died from earthquakes and 2010 has seen a single event killing more than 200,000 people (Haiti 2010). Bilham suggested in the conclusions of his Mallet Milne lecture in 2009 that the global death toll from moderate earthquakes near human settlements is likely to average 8,000–10,000 a year in the next several decades and catastrophic events may bring this up to 50,000 deaths per

year. A direct “hit” of a $MW \geq 7$ earthquake in Tehran will cause more than a million deaths (Bilham 2009). As shown in Fig. 2, the number of megacities in this figure depicts cities with over a million people are aplenty and the seismic risk of some of these cities are high. For many cases traversed by active faults, this is due to what Jackson (2006) calls it the *fatal attraction*. For many centuries, an uneasy accommodation was reached between human needs and the earthquake-controlled landscape, sometimes brilliantly exploited by local hydrological engineering, as in Iran. In the past occasional moderate earthquakes would occur, killing a proportion of relatively small population. However, many once-small rural communities have now grown into towns, cities, or megacities while retaining their vulnerability through poor building standards.

As witnessed in recent years, earthquakes that occur in these places now kill many more than they did in the past and there are other cities like capitals as well, like Kathmandu in Nepal which is highly at risk. Extreme catastrophes have been rare only because the exposure of modern megacities to earthquake hazards has been relatively

Earthquakes and Their Socio-economic Consequences, Fig. 2 Population map of Asia showing the megacities at risk (Credit: GEM)

short (approx. 50 years); an increase in the number of such catastrophes now seems to be inevitable., e.g., Tehran, as shown in Fig. 3.

The most used parameter to measure the social impact or severity of an earthquake is fatalities, but in terms of social consequences, it is the survivors that need the humanitarian assistance in the short term and committed recovery and reconstruction plans to rebuild shattered lives in the long term. After the initial relief phase, the “fate” of those affected is the responsibility of those in governance, e.g., the establishment of the Canterbury Recovery Authority (CERA) after the Canterbury Sequence in 2010–2011. Possible indicators to help measure and monitor long-term social and economic recovery are highlighted in the section “[Recording Socio-economic Consequences.](#)”

Table 1 shows how earthquake severity is usually reported in terms of total losses, insured

loss, and fatalities. Apart from the two earthquakes in Japan (Kobe 1995; Tohoku 2011), there is an inverse relationship between property losses and casualties – high losses and low fatalities in developed counties and low insured losses and high fatalities in undeveloped or developing countries. The Great East Japan earthquake and tsunami as shown is the single most costly event since 1980, reporting overall losses of over US \$210 billion. This earthquake was exceptional in many ways, not least because of the high fatality rate in a highly developed exceptionally well prepared country. It is important to note here that with a better understanding of parameters like vulnerability and exposure, losses and casualties are now only loosely associated to physical variables such as magnitude.

More assessments on the economic and insured losses can be found in Chapter 29 of this volume.

Earthquakes and Their Socio-economic Consequences, Fig. 3 The city of Tehran with the active North Tehran Fault as a backdrop (Credit GEM)

Earthquakes are usually reported by insured losses and casualties, though the effects of an earthquake can be generally classified into the following categories:

1. Physical impacts
2. Social impacts (the impact on people)
3. Economic impacts (the impact on the wealth of an area)
4. Environmental impacts (the impact on the landscape)

These can be immediate or long-term consequences and most are entirely interlinked. For example, damage to a transportation system due to ground shaking in an earthquake can take years to repair and therefore contribute significantly to the business and economic losses in the area affected. In a study on transportation disruptions from the Northridge earthquake in 1995, it was reported that 43 % of the businesses surveyed attributed their losses at least partially to

transportation disruption (Boarnet 1995). In the future, disruption of electronic networks may also be crucial, as there is a huge dependency of businesses on ICT.

After the February 2011 earthquake in Christchurch, New Zealand, the majority of businesses in the center business district (CBD) had to relocate. In the week after the quake, people at the Canterbury Earthquake Recovery Authority (CERA) described how everyone was on the phone trying to find a place and negotiate a lease. In some cases this involved multiple locations. Inland Revenue staff, for example, are scattered in 300 different offices. Some firms have moved to residential or semi-industrial areas and others have relocated to other cities. Tourism declined and tertiary education was under pressure. A City Council survey suggests that over 60 % of businesses that moved out wanted to return to the city and the CBD was already under pressure from a number of peripheral shopping malls, though 51,000 people were

Earthquakes and Their Socio-economic Consequences, Table 1 Table of the most costly earthquakes since 1980 (MunichRe)

			Overall losses	Insured losses	Fatalities
Date	Event	Affected area	US\$ m, original values		
11.3.2011	Earthquake, tsunami	Japan: Honshu, Aomori, Tohoku; Miyagi, Sendai; Fukushima, Mito; Ibaraki; Tochigi, Utsunomiya	210,000	40,000	15,840
17.1.1994	Earthquake	USA: CA, Northridge, Los Angeles, San Fernando Valley, Ventura, Orange	44,000	15,300	61

still working in the center. This real-life scenario is very reminiscent of Kates and Pijawka (1977) model of recovery from earthquakes.

The main actors helping businesses after the earthquakes of 2010–2011 were the Chambers of Commerce, Canterbury Development Corporation, Christchurch City Council and other local authorities, central government, and CERA. The City Council relaxed regulations allowing businesses to relocate to residential areas in the west and to new retail hubs. This however only aggravated the problem of attracting business back to the center. In Christchurch it is estimated that NZ\$20 billion will be invested in the city and 15,000 jobs created in construction (Fig. 4).

The overall vision for the city was to give investors confidence. However, some of the risks and problems the city still faces include a flight of capital in which property owners are

choosing not to reinvest in the city center or Christchurch; the scale of the demolition and the time taken to rebuild and owners of tall buildings that require demolition are holding the city to ransom for months and months. The last cordons to the CBD were lifted in June 30, 2013, 859 days after the earthquake. Whether Christchurch will recover financially from the earthquakes remains to be seen.

In stark contrast to pure financial costs are social and psychological consequences that are hard to quantify but the effects of which will be felt for a long time after the disaster. The inundation of the tsunami in schools in the East Coast of Japan in 2011 and the collapse of school buildings after the Wenchuan earthquake in China in 2008 killed an entire generation of school children (Fig. 5).

Effects are often ordered as primary and secondary impacts. Primary effects occur as a direct

Earthquakes and Their Socio-economic Consequences,

Fig. 4 Christchurch city center closed to the public (Taken by the authors, February 2012, a year after the second more devastating event)

Earthquakes and Their Socio-economic Consequences,

Fig. 5 Unclaimed children's satchels are left in a former gymnasium at Arahama School in Japan after the Great East Japan earthquake and tsunami in 2011 (Authors' own)

result of the ground shaking, e.g., buildings collapsing. Secondary effects occur as a result of the primary effects, e.g., tsunamis or fires due to ruptured gas pipelines. The table below summarizes the range of possible consequences from earthquakes (Table 2).

With urbanization, the world's population is increasing in hazardous areas and people are

living more densely. Rapid development has meant that even with the strongest of political and economic will, the pace of regeneration of building stock is outrunning the return periods of earthquakes (Bilham 2009). Perhaps the only way to engage with earthquake-prone communities in mitigation is through social and fiscal means, rather than purely physical interventions.

Earthquakes and Their Socio-economic Consequences, Table 2 Summary of possible consequences of earthquakes

	Physical impacts	Social impacts	Economic impacts	Environmental impacts
Short-term (immediate) impacts	Buildings, transportation, and infrastructure systems damaged as well as critical facilities	People may be killed or injured. Homes may be destroyed. Transport and communication links may be disrupted. Water pipes may burst and water supplies may be contaminated. Families may be separated	Shops and business may be destroyed. Looting may take place. The damage to transport and communication links can make trade difficult	The built landscape may be destroyed. Fires can spread due to gas pipe explosions. Fires can damage areas of woodland. Landslides may occur. Tsunamis may cause flooding in coastal areas
Long-term impacts	Relocation of villages and towns	Lack of healthcare provisions for the affected. People may have to be rehoused, sometimes in refugee camps. Psychological distress and chronic injuries. Family stress and disruption	Job losses and financial strain on the community for reconstruction may be significant. Investment in the area may be focused only on repairing the damage caused by the earthquake. Long-term fiscal impacts and business failures	Important natural and cultural landmarks may be lost

Characteristics of Socio-economic Consequences

The direct, indirect, and long-term socio-economic consequences of earthquakes need to be carefully considered when devising disaster mitigation plans and strategies for urban development. The figures of losses from earthquakes shown in Table 1 raise an interesting question of how these parameters are calculated and recorded, for example, what do overall losses mean? How are other socio-economic measurements made? Decision makers charged with recovery need to understand the important socio-economic consequences of earthquakes.

What is the definition of a displaced person? In Alexander (1985), he discussed the difficulty of defining the dead and injured. What are the cutoff points of reporting? An important agenda for the Integrated Research on Disaster Risk (IRDR) organization, whose goal is “to develop trans-disciplinary, multi-sectorial alliances for in-depth practical disaster risk reduction research studies, and the implementation of effective evidence based disaster risk policies and practice,”

would be to improve the definition and accuracy of social and economic parameters so that options for investment in mitigation and disaster preparedness might be compared and contrasted

One of the organization’s priorities is to focus on the collation and standardization of loss data through a data working group. The ambition is to enable decision makers to make informed decisions on actions to reduce the impacts of natural disasters. The existing records and a review of global efforts, including that of the Global Earthquake Model (GEM), to standardize the collection of socio-economic consequences through the Earthquake Consequences Database (GEMECD) in collaboration with CRED are described in the section below.

Recording Socio-economic Consequences
Records of socio-economic consequences can be difficult to obtain and hard to compare. Individual case studies carried out by engineers and social scientists give details of the exact consequences of the event at the time of reporting, but these are seldom comparable with other events and therefore cannot be relied on for deriving specific

Earthquakes and Their Socio-economic Consequences, Fig. 6 Graph shows normalized damages in the USA 1900–2005 from Vranes and Pielke (2009) where the 1906 was found to be the most costly event in US history

mitigation strategies for other areas. The need for accurate and comparable numbers cannot be underestimated as they help a community of seismologists and engineers communicate risk to economists and politicians. What are the true costs of earthquakes? Socio-economic figures are meaningless unless placed in context and normalized in terms of population size and demography. For example, what was the absolute number of people killed, as a percentage of local population? What is the cost of the earthquake in today's terms? For example, a study by Vranes and Pielke (2009) on twentieth-century US earthquakes found that if normalized to 2005 dollars by adjusting for inflation, increased in wealth, and changes in population, the 1906 San Francisco earthquake would most likely to have been the most costly US earthquake, at

US\$328 billion, though some would still argue about the definition of "cost." Clear standardized definitions would help to reduce this ambiguity and inconsistency. This question could be answered partially by distinguishing between direct and indirect costs and short- and long-term costs. Some studies report the number of households affected, while others report the number of people. The reporting of social data is also dependent on the experience and training of interviewers and surveyors. Often samples are poorly constructed, interviewing is inconsistent, and questionnaire forms are badly designed (Fig. 6).

Knowing when essential services and livelihood are restored would capture some key aspects of recovery. But another issue with existing socio-economic data is that they lack

date stamping, for example, it is insufficient to know the number of homes without electricity or water supply or the number of homeless or unemployed; one also needs to know the time period of loss.

The indicator “number of people in homeless,” for example, is also time dependent. The term “homeless” can apply to any of the following:

- People taking shelter in an organized camp or in an organized shelter building (e.g., school, sports hall, etc.) – these are facilities providing short-term shelter, having communal kitchens and bathrooms.
- Number of people taking or given the option of alternative accommodation (with or without public subsidy), e.g., rent another home, rent a room in a hotel or hostel, and be hosted by relatives or friends or volunteers (usually after the first week following the event).
- Number of people provided temporary housing units (usually more than 1 month after the event) – these are usually prefabricated homes with minimal facilities intended for occupation no longer than 1–2 years.

In the simplest case, there should be two categories for the homelessness data: “number of homeless in the immediate aftermath” and “number of homeless for a significant duration of time.” This is a crucial differentiation. If not directly available these two categories of homelessness can be derived from damage statistics. Long-term homelessness would be related to the estimated population in destroyed houses or collapsed and red-tagged houses; homelessness in the immediate aftermath would be related to the estimated population in houses with serious structural damage that were deemed unsafe for immediate occupancy after post-earthquake damage/safety assessments, e.g., the number of yellow-tagged dwellings – depending on the damage reporting style in each event, country, and region. Long-term homelessness (usually more than 1 month) would imply people who have lost their homes due to ground shaking damage or due to secondary and induced hazards,

such as liquefaction, landslide, tsunami, or fire following, or because of abandonment/relocation of their neighborhood, village, or town (due to occurrence or high risk of occurrence of landslide, mudslide, rockfalls, liquefaction, fire following, tsunami, risk of dam collapse, nuclear disaster, other hazardous substance release, etc.), even if their homes were not destroyed.

An additional (and important) indicator, related to recovery, is the speed of reconstruction of the dwellings that were destroyed. Recovery can be expressed as a percentage of destroyed houses that have been reconstructed by a given time after the event, e.g., 1 or 2 years after the event (high-consequence events take several years until full recovery is achieved even in the most developed regions of the world).

An example of the recovery of the destroyed dwellings during the first 2 years after the September 7, 1999, Athens earthquake is given below:

- On the first anniversary of the earthquake, the Greek Ministry of Environment and Public Works released the following information: more than 50 % of the red-tagged housing units (i.e., housing units that are not habitable or usable in its current state) are being reconstructed (2,503 out of 4,220).
- On the second anniversary of the earthquake the Greek Ministry of Environment and Public Works released the following information: out of a total of 4,682 red-tagged buildings, 70 % had received reconstruction funding, and 400 (8.5 %) were part of a government-funded regeneration plan in the worst affected and poorest municipality of Ano Liosia and in Nea Philadelphia municipality (expected to be completed 42 months after the occurrence of the earthquake).

Records of socio-economic consequences help track progress of recovery through time that can be used as an accounting measure for donors and provide an insight into the possible issues contributing to delays in recovery of the economy (lack of housing, infrastructure, educational facilities, etc.).

Towards a Standardized Process of Recording and Reporting Socio-economic Consequences

GEMECD is the Global Earthquake Model (GEM) Earthquake Consequences Database. GEMECD is GIS relational database and is a repository of the most relevant and validated data on consequences of the significant events of the future and for the last 40 years around the world. Under the auspices of GEMECD and IRDR, the Centre for Research in Epidemiology and Disasters (CRED) has devised, together with MunichRe and CAR Ltd., a set of 45 key socio-economic indicators for earthquakes. The earthquake impact indicators are divided by type into social, social-recovery, and economic indicators. Generally indicators are mostly applied to entire affected area where impact has occurred, but in certain situations, the indicator may only refer to a reduced area because data is unavailable. Indicator specification, therefore, is based on an optimal situation. Moreover, indicators can be measured for the affected area or for the entire affected country. Which of these is used for a defined area is governed by the source of information.

Attempting to measure all 45 socio-economic indicators in any given post-disaster context is the desirable objective, but data availability constraints mean this is not always feasible. Quite often multiple sources of data are required to measure all indicators (e.g., reinsurance companies such as MunichRe or SwissRe, international organization situation reports such as produced from the United Nations Office for the Coordination of Humanitarian Affairs (OCHA) or the International Federation of Red Cross and Red Crescent Societies (IFRC), Post-Disaster Needs Assessment (PDNA) case studies, such as the ones conducted by the World Bank (WB)). Consequently, this may lead to slight variations exist in estimates and totals.

The socio-economic consequences data for the 18 events in the GEMECD is the most comprehensive set of verified information to be stored in one single repository. The database sets a global standard for future earthquake consequences data collection with a standardized set of 45 indicators, which now also forms part of the IRDR loss data guidelines document (So et al. 2012).

Causes of Socio-economic Consequences

Underlying all of the 45 indicators is the social status and structure of an affected community. The severity of social and economic consequences on a society and its ability to recover depends very much on the sociodemographic characteristics, perception of and experiences with earthquakes, and its overall capacity to respond.

In simplistic terms one can categorize socio-economic effects according to state of development of different countries – high-, medium-, and low-income countries. The chart below is taken from a study carried out by Spence (2007), comparing the relative progress made in the reduction of preventable deaths with public health campaigns and earthquake deaths in the same period. As shown, for high Human Development Index (HDI) countries, the line shows a relatively stable reduction of earthquake deaths from its initial levels, but globally, the red line shown suggests the community is not doing enough to prevent deaths in undeveloped and developing countries. The Human Development Index (HDI) is a composite statistic of life expectancy, education, and income indices used to rank countries into four tiers of human development (Fig. 7).

If one selects just some of the most significant earthquakes of the last two decades and reviews the number of fatalities and the direct economic costs (GEMECD 2014), one can immediately see the differences between low-HDI countries and high-HDI countries, in terms of, crudely put, cost per fatality. Obviously there are many gross assumptions made here, and there are many other factors such as governance, culture, and other social factors that come into play as well as the size of the event. The numbers are not directly comparable; direct economic losses are at the time of the event and not inflation adjusted and the HDI is taken in 2012, but a vague relationship does emerge. It costs more per fatality in high-HDI countries (Table 3).

The disproportionate effects of an earthquake on the poor, for example, are well researched and not at all surprising, as the socially vulnerable group reside in older, poorly built housing more prone to damage during an earthquake and the

Earthquakes and Their Socio-economic Consequences, Fig. 7 Graph comparing the progress made in reduction of deaths in earthquakes and other public health issues (up to 2000)

likely capital required to rebuild and recover is not readily available after the event. Broadly speaking one perhaps can venture to summarize the likely socio-economic consequences of earthquakes for different countries in the following way (Table 4).

Though perhaps the overall level of wealth of a country is not as fundamentally diagnostic of its earthquake vulnerability as is its differential between rich and poor.

The recent earthquake and tsunami in East Japan has also highlighted the need to anticipate the risk to the future population in earthquake-prone regions. About half of victims of this earthquake were elderly people of 65 years old or more, unable to respond to warnings and evacuate in time. Based on the statistics presented by Statistical Information Institute for Consulting and Analysis, depopulation has extended over the whole region, excluding large metropolitan areas such as Sendai. Forty percent of all municipalities will experience a population decrease of 20 % or more, accentuating the pre-disaster condition. In coastal areas of the Pacific Ocean, population is anticipated to decrease even further

since local economies were destroyed and young people will leave as a result (Masateru 2011).

The preexisting socio-economic trends in a region are likely to be amplified by a major disaster. Places that were shrinking before the disaster may be pushed into severe decline. Industries that were struggling to survive may fold and young people may move elsewhere in search of work. Conversely places that were booming before the disaster, or where the economic conditions were propitious, may experience a spurt in growth as opportunities open up and money flows into the area, e.g., Kobe, Japan. Much of the Tohoku region, for example, was in economic and demographic decline before 2011 and, despite the huge investment in the region, the earthquake has exacerbated the situation.

The risk of vulnerability and the impacts of disaster are disproportionately borne by those who are already socioeconomically and physically disadvantaged and who have fewer resources to enable them to “bounce back” to some measure of normality. These include foreign nationals, the very young and very old, those

Earthquakes and Their Socio-economic Consequences, Table 3 List of 10 significant earthquakes in the last 20 years and their socio-economic consequences (high HDI, 0.758; medium HDI, 0.64; low HDI, 0.466)

Earthquake	Fatalities	Direct economic losses (million US\$) ^a	“Cost”/ fatality (million US\$)	HDI	Lessons learned (from reconnaissance)
Northridge, Mw 6.7 (1994)	61	44,000	721	0.937	Severe damage to hitherto deemed safe steel-framed buildings
Kobe, Mw 6.9 (1995)	5,502 (fires)	96,000	17.4	0.912	Revised building code and nationwide retrofit Sch. of traditional timber residences
Kocaeli, Mw 7.4 (1999)	17,118	11,400	0.67	0.722	Building control called into question; new RC buildings performed worse than older traditional ones
Athens, Mw 5.9 (1999)	143	3,395	24.1	0.86	45 % of fatalities were in industrial buildings
Bhuj, Mw 7.7 (2001)	13,800	4,405	0.32	0.554	Site effects were significant on extremely weak masonry
Bam, Mw 6.6 (2003)	26,271	500	0.019	0.742	Extremely vulnerable dry mud brick buildings. 26 % of Bam died
Wenchuan, Mw 7.6 (2008)	>73,000	141,000	1.93	0.699	Bad siting of towns and schools killed many
Haiti, Mw 7.0 (2010)	>230,000	4,245	0.018	0.416	Extremely vulnerable substandard buildings
Christchurch, Mw 6.1 (2011)	185	16,000	86.5	0.919	Collapses of two mid-rise RC buildings accounted for 70 % of the deaths. People were killed on the streets by out-of-plane failure of masonry debris
Great East Japan, Mw 9.0 (2011)	>18,100 (tsunami)	211,753	11.69	0.912	Deaths from earthquake were ~150; tsunami heights were significantly above design allowances. Revisit nuclear facilities design

^aAll the data has been taken from the GEM Earthquake Consequences Database (GEMECD)

Earthquakes and Their Socio-economic Consequences, Table 4 Table relating HDI to socio-economic consequences of earthquakes

Consequences	High-HDI countries	Low-HDI countries
Casualties	Low	High
Property damage	Low	High
Cultural change	High	Low
Economic disruption	High	Low
Environmental damage	Moderate	High

living in poverty, ethnic minorities, the physically and mentally disabled, and women – especially those who are poor, pregnant, lactating, or elderly.

Observations on Gender

For some types of natural disaster, in particular earthquakes and tsunamis, there is evidence of a higher fatality rate in women than in men, and it seems that women may be more vulnerable than men to major unexpected hazards such as earthquakes, fires, tsunamis, or terrorist attacks. This vulnerability may occur because women have a slower reaction time than men or due to poor decision making. Alternatively, it may result from cultural factors, such as the way that women are subservient to or dependent upon men in so-called “traditional” societies.

Although there is a considerable body of evidence that building quality is the most significant factor in the number of fatalities in sudden-

impact disasters such as earthquakes, this fact alone does not account for gender differences in casualty rates. Because the gender division of labor keeps women in or close to homesteads, Byrne and Baden (1995) argued that it is generally they who suffer disproportionately from the collapse of poorly constructed dwellings.

A clear relationship has been found between the number of buildings that collapse in an earthquake and the number of fatalities caused. Mortality is therefore related to the chance of being in a poorly constructed building at the time of the disaster. Timing is clearly important. For example, there may be a higher death toll of both men and women if a disaster happens at night when people are asleep and a higher death toll among women if it happens during the day when men are away from the home. If death rates are higher among women, it could be because:

- Women are more likely than men to be caught in poorly built buildings, for example, by being more likely to be at home.
- Women are more likely to be caring for young children or elderly relatives who slow their evacuation.
- Women are likely to be older, since women live longer.
- In some societies, women tend to be less well educated and make poorer decisions in a crisis.
- Women less likely to evacuate rapidly, because they are more inhibited about leaving the home.
- Women are more likely to be caring for dependent children or elderly relatives.
- Again in some societies women are generally of lower economic and social status and have less access to resources.

It has been also suggested that women have a greater propensity to sacrifice themselves, for example, by rescuing young children or elderly relatives, rather than escaping on their own, but this has never been proven by field evidence. Alternatively, there may be gender differences in attitudes to risk-taking behavior that influence mortality.

Hatch and Dohrenwend (2007) also pointed to the lack of research evidence on the distribution of the events according to gender, age, racial and ethnic background, and socio-economic status (SES). They suggest that such information would help identify groups at greatest risk so that they could be investigated further. Although, theoretically, the impacts of a disaster are not randomly distributed across socio-economic classes, empirical evidence of this claim is scarce. In a population-based cohort study of the 1999 Taiwan earthquake, the multivariate results suggest that health status and socio-economic status (SES) are likely to be two key predictors of earthquake mortality. Indeed, lower SES, major disease status, and moderate physical disability status increased the risk of earthquake death 1.5– 2.5-fold (Chou et al. 2004). It is necessary to understand how socio-economic status and health interact with gender in such cases. In one of the greatest modern disasters, the Indian Ocean tsunami in 2004, more women than men died.

Women's and men's decisions in times of crisis have been shown to differ along risk-taking lines, nature of coping strategies, adaptability, and advice-taking and information-seeking behaviors (Dankelman et al. 2008). Hazeleger (2013) examined gendered disaster recovery issues relevant to Australian policy and also found differences in disaster risk taking as well as economic differences and inequalities that affected survival and recovery between men and women. This calls into question the assertion that high levels of economic development iron out the risk levels between men and women.

Two Events in the Twenty-First Century

In this section the socio-economic consequences of two real events – the L'Aquila earthquake of 2009 in Italy and the Great East Japan earthquake and tsunami of 2011 – are examined. These two earthquakes represent the most socially controversial and most costly events in the past decade. The intention here is not to generalize about how certain decisions pre- and post-event would help a

society recover more effectively. The purpose of this section is to describe the implications of earthquakes on two very different communities and in doing so draw the readers' attention to the complex long-term social and economic consequences of earthquakes. The consequences of earthquakes go far beyond the immediate aftermath of the event and can adversely or positively impact on future generations. Comparing the management of these two disasters and assessing the key overriding factors on recovery. What are the true costs of earthquakes and at whose expense? In reviewing the evidence on the recovery of the, four central themes were found namely:

1. Government plans for reconstruction
2. Socio-economic characteristics of the region
3. Citizen involvement in decision making
4. Politics and the media

The following sections are therefore organized accordingly.

Reflections on 2009 L'Aquila in Italy

The Mw 6.3 L'Aquila earthquake caused 308 deaths and nearly 1,200 injuries of which 202 were serious. This was the deadliest earthquake in Italy since the November 23, 1980, earthquake in the region of Campania and the most destructive earthquake in L'Aquila since the series of three earthquakes that devastated the wider region in January and February 1703 that killed at least 10,000 people. In 2009 203 people died in L'Aquila, a city of 73,000 inhabitants, and many more thousands are students of the L'Aquila University, not living in the city, while in the village of Onna, 38 out of around 350 inhabitants were killed. The hospital at L'Aquila, where many of the victims were brought, suffered damage in the 4.8 aftershock which occurred one hour after the main earthquake and had to be partly evacuated. Damage to L'Aquila's and wider regions' historic buildings and churches was also quite severe.

In total, almost 4,000 buildings collapsed or were damaged beyond repair, while another 70,000 buildings were damaged but repairable, and 65,000 were made homeless. In a report to

the EU, the Italian government estimated the cost of the earthquake at just over €10 billion while insured losses reached \$US250 million. Four months after the event, the Italian Civil Protection reported 49,000 people were still homeless.

Government Plans for Reconstruction

Unlike the management of past earthquakes in Italy, the central government under Berlusconi promised that the affected population would not be placed in transitional housing which usually came in the form of mobile trailers or prefabricated housing. The homeless were housed in camps around the affected area and in various hotels along the coast. The process of reconstruction was entirely led by the Italian Civil Protection Authority (DPC), and the aim was to reconstruct and rehouse the affected population within a year in 19 new towns. This was led entirely by the central government at a cost of €1.6 billion. The name of this project was the C. A.S.E. (Complessi Antisismici Sostenibili ed Ecocompatibili (Calvi and Spaziant 2009). According to the Italian government, nearly €8 billion has been spent on L'Aquila and the 56 surrounding communities that were affected in the quake (BBC 2013). This housing provision has sparked controversy though. The fact that all of these new towns are far away from the main city and are not accessible by public transport has been a source of major discontent (Alexander 2012), though the rehousing of the affected population has taken place very swiftly (Fig. 8).

Socio-economic Characteristics of the Region

L'Aquila is the largest city in the region and, with a GDP of €27,703.41 million, is the wealthiest region in Central Italy, hosting a university. The surrounding villages like Onna and Paganica are predominantly home to small businesses or second homes. The city's work force is mainly concentrated in public services such as defense, manufacturing, service industries, and the building industry. The death toll might have been much worse, if many more day visitors and students had been in the city, inside and outside vulnerable buildings.

Earthquakes and Their Socio-economic Consequences, Fig. 8 A C.A.S.E. town on the outskirts of L'Aquila

Abruzzo has traditionally relied on agriculture, but there has been some industrial growth especially in engineering, food, transportation, and telecommunications sectors in recent years; though by comparison with its northern neighbors, the Abruzzo region is not a major industrial center and the industry is on the coast, two hours' drive from L'Aquila. The fact that there were relatively little financial losses in terms of business interruption may be a key factor in the slow pace of overall recovery and reconstruction. Contrasting L'Aquila's situation is the recovery of the wealthy Emilia-Romagna region, one of the most industrialized areas of the country. Two major earthquakes Mw5.8–5.9 caused 27 deaths and more than €12 billion euros of damage in May 2012, seriously affecting small- and medium-sized companies. The earthquake disrupted more than 10,000 companies in the affected areas. There was an urgency to be back in business and private companies were the main drivers of the recovery of the region. The symbolic "solidarity cheese" fund brought in around €1 million. People all over Italy were encouraged to purchase the damaged wheels of Parmigiano-Reggiano and Grana Padano cheese, produced in and around the city of Parma, to help with the region's economic recovery.

Unlike other Northern Italian cities, the charming historic center of L'Aquila does not attract many tourists, probably due to its geographical location. Despite the initial heroic remediation measures, the historic center still lies derelict with scaffolds supporting the structures, but little else is being reconstructed or considered. All attention was focused on building new settlements, and perhaps L'Aquila's reconstruction was never the major focus of attention from the start since the town center does not have the social clout to demand the attention of the central government. In a recent article by the BBC (2013), it was reported that some 22,000 of the 70,000 people of the city who were made homeless are still unable to return to their homes and are living in new blocks of flats on the outskirts. Some 70 % of the reconstruction needed on the outskirts has been completed, but the thirteenth-century town center remains crippled, guarded by the military who only allow those with authorization to enter.

What will become of L'Aquila's historic center? 4 years on and the center is still littered with unusable buildings; commercial activity is much reduced and public services deteriorated; it is hard to imagine how its fortunes can be reversed (Fig. 9).

Earthquakes and Their Socio-economic Consequences,

Fig. 9 L'Aquila city center 2012 – abandoned and cordoned off, the medieval buildings propped by scaffolding (BBC 2013)

Citizen Involvement in Decision Making

There has been a lot of criticism of the authorities handling of the reconstruction process after the L'Aquila earthquake. A recent report suggested that there had been no public participation in the reconstruction planning of the new towns around L'Aquila. A top-down approach was used under the pretext of a more rapid reconstruction strategy and recovery of the region. However "Once people have been housed in accommodation that will last for years, they can be forgotten, or at least left to better their circumstances without further state intervention" (Özdem and Jacoby 2006). The decision to create the surrounding new settlements seems to lack long-term vision and will inevitably change the residents' daily lives. As recounted in an interview for the BBC:

I miss my former life, the neighbours I grew up with, the woman who lived upstairs who used to treat me like a daughter . . . I want the L'Aquila we all know to return and be even better, I want people to come back. (L'Aquila_) is an oasis among dozens of empty, damaged buildings," says Mariella Riccobono, who now lives 10 min outside the town. Wiping a tear from her cheek, she says: "It's worth fighting for your home. If you give up, you're abandoning the city. We've continued paying a mortgage all this time and it's my livelihood, it's everything I've created.

Politics and the Media

The media and politics were never far from L'Aquila immediately following the earthquake

in April 2009, with the Prime Minister's 23 visits to the region and his decision to bring the 35th G8 summit to L'Aquila in July 2009, 3 months after the earthquake hit the region. The need to secure votes in provincial elections by Prime Minister Berlusconi's Government only weeks after the disaster was perhaps the incentive behind a centralized top-down approach to the rehousing projects in L'Aquila, crucially ignoring local public opinion (Fig. 10).

However, once the cameras and world leaders left and votes for the provincial elections were secured, the town center was left alone. In a recent article in the BBC (2013), Mayor Massimo Cialente accused the government of forgetting about L'Aquila. He says the delay has been due to paralyzing bureaucracy, a lack of organization between the local and national governments, and a lack of funds. But reconstruction is more easily said than done in a city where many of the buildings are centuries old, where homes are interwoven with historically important buildings, and where the narrowness of the streets means cranes and other construction vehicles can only be brought in a few at a time.

Reflections on the Great East Japan Earthquake and Tsunami of 2011

The earthquake and tsunami devastated Tohoku and other regions. In total by the 18th month after the event (September 2012), around 1,230,000 buildings were recorded as having

Earthquakes and Their Socio-economic Consequences,

Fig. 10 World leaders at the G8 visit L'Aquila July 2009 (Photo courtesy of Reuters)

E

Earthquakes and Their Socio-economic Consequences,

Fig. 11 Devastation caused by the Great East Japan earthquake and tsunami (Copyright EPA)

been damaged or destroyed due to tsunami and ground shaking (which is equivalent to 2.4 % of all of Japan's existing buildings) and the tally continues. Life loss is reported as 20,721 and includes 2,303 earthquake-related deaths that occurred due to various causes after the day of the earthquake.

In terms of cause of death (21/4/2011):

- 92.5 % drowned.
- 4.4 % crushed/died of injuries.
- 1.1 % burnt.
- 2.0 % unknown (Fig. 11).

According to MunichRe, the overall losses of this event are estimated to be over US\$210 billion. The monetary cost associated with the failure of the Fukushima Daiichi nuclear power plant as a result of the 14 m tsunami is still not quantified to this day, though Tokyo Electric Power Company (TEPCO) announced a ¥1.02 trillion cost of natural disaster. Immediately after the disaster, approximately 85,000 people were evacuated from 20 km evacuation zone and 185,000 people were screened for contamination. Less serious problems occurred in the Onagawa and Fukushima Daini nuclear power plants.

Earthquakes and Their Socio-economic Consequences, Fig. 12 Locations visited by the UK Earthquake Engineering Field Investigations Team mission (EEFIT 2011)

The strongest tsunami consequences occurred (north to south) from the town of Fudai (in northern part of Iwate Prefecture) down to Iwaki (in the southern part of Fukushima Prefecture). In total it was estimated that around 600 km² of land was flooded, where around 600,000 people lived. Around 18,500 people are dead or missing as a result of the tsunami, with

the worst effects occurring in Miyako, Yamada, Ofunato, Otsuchi, Kamaishi, Rikuzentakata, Minami Sanriku, Kesennuma, Onagawa, Ishinomaki, Higashi Matsushima, Tagajo, Sendai, Natori, Watari, Iwanuma, Yamamoto, Soma, Minami Soma, Namie, Shintchi, and Iwaki (Fig. 12).

In terms of critical facilities, networks, and infrastructures, the power, gas, and water supplies were disrupted in many areas, mostly in the Tohoku region. Roads, railways, ports, airports, and other infrastructure were also damaged. Damage to roads was recorded in all eastern prefectures between Iwate and Kanagawa (in total 4,188 damaged roads of which 2,343 were in Chiba Prefecture). Almost all roads have been reopened quite rapidly, including the Tohoku Expressway, most of the Joban Expressway, as well as national highways. Damage to 116 bridges was recorded, of which 97 were in the Kanto region.

There were also significant secondary hazards other than the tsunami. Landslides were recorded in 208 locations and caused the loss of 19 lives (including 12 killed by the Hanokidaira landslide in Shirakawa city of Fukushima Prefecture). Extensive liquefaction occurred on the northern shores of Tokyo Bay particularly in Urayasu town (Chiba Prefecture). Fires occurred in the Cosmo Oil's refinery in Ichihara town (Chiba Prefecture) as well as in Kesennuma and Natori (Miyagi Prefecture) during and after the tsunami.

It must be noted that the damage, loss, and human casualty data given here originate from Japan's Fire and Disaster Management Agency (FDMA) report issued on the first-year anniversary of the event and are not the final figures, as efforts continue to assess all the consequences of this tremendous earthquake.

The information and reflections in the subsequent sections on the factors affecting the recovery of the Great East Japan earthquake and tsunami have been put together by the authors' visit to the affected area as part of the UK's Earthquake Engineering Field Investigation Team (EEFIT) reconnaissance mission in June 2013.

Government Plans for Reconstruction

One of the key issues found when reviewing the plans for reconstruction is how much room for adaptation there is in the application of the central government's template for recovery (EEFIT 2014). Japan is a compliant society, and there may be more flexibility than bureaucrats or residents realize. But no one has any inkling about the cost-benefit of the huge investment. This is a national response to disaster, but there are differing opinions in the local area in terms of priorities and decision making.

The Reconstruction Agency was established by the Prime Minister's Office. It advises government on all basic strategies based on quick lessons. But hard solutions give a false sense of increased security and early warning is an issue. The reaction of government has been self-critical. Instead of defending the system, they have been frank about what failed and it is in the character of Japan to always review and look back and learn lessons (Bhatia et al. 2013). For example, ideas about evacuation are changing. Japan national broadcasting has changed the way it announces the early warning. Rather than giving precise information that is open to error and misinterpretation, it will from now on give much simpler direct warning to evacuate immediately.

The focus, at the time of the EEFIT mission in June 2013, has been on relocating housing and safety measures, whereas the imperative is to strengthen the local economy and address economic and demographic decline. Measures that would strengthen existing local businesses and city center shops, attract new industry, and encourage young people to the city might also have been considered. One thing the central government might have considered is founding a college of higher education, either a new university or a branch of a university in Sendai, preferably one that focused on technology and had practical links with industry and enterprise.

There is a proposal from Kobe University to revitalize small business, but people in the affected area do not have the resources or money to take action or to exploit new technology. New people would be most welcome. Do people take the initiative and accept

Ages of those who lost their lives in the Great East Japan Earthquake and Tsunami, 2011

Earthquakes and Their Socio-economic Consequences, Fig. 13 A breakdown of ages of the dead in the GEJ earthquake and tsunami of March 2011, of those 5,971 were male and 7,036 female

responsibility or do they expect people to come and help solve the problem? People with initiative would be a good thing. People have been here a long time and cannot see how to fix the problem.

Socio-economic Characteristics of the Region (Pre- and Post-disaster)

A breakdown of the ages of those who died in the disaster revealed a disproportionate percentage of the elderly were affected; 65 % of those that lost their lives were over 60 years old as shown in this graph (Fig. 13).

Population emigration due to the disaster is largely occurring among young people. The International Recovery Platform pointed out the issues being faced by the affected areas following the Great East Japan earthquake are compounded by the problem of shrinkage confronting most rural towns in Japan. In addition to issues of safety and relocating housing, population decline, ageing, and economic shrinkage pose special planning challenges (International Recovery Platform 2012).

It is hoped that tackling these issues by reordering land use, improved transportation links, and urban center regeneration projects will have a positive impact on the prospects of these places as well as make them more resilient to a future disaster.

Not all places that were affected by the tsunami are the same, however. The area around Sendai in Miyagi Prefecture is a flat plain and has a strong economy, good transport links, and a growing population. Further north in Iwate Prefecture, there are steep slopes and fiords, a declining population, and a weak economy. In each there are differences of scale with a few larger cities and towns and many smaller settlements and villages. This suggests that different places face different issues of recovery. These differences in socio-economic prospects, demography, topography, and scale suggest that approaches to both safety issues and economic development assistance might be fine-tuned to meet local circumstances.

Citizen Involvement in Decision Making

In the areas affected by the 2011 tsunami, consultations between governments and communities were the rule, and community representatives were invited to serve alongside experts on recovery planning committees from the earliest stages. The most common ways of collecting residents' opinions were surveys and workshops. The central government and local governments outside the disaster-affected area helped affected municipalities plan their recovery by conducting research, seconding staff, and hiring professionals to provide technical support. University faculty members, architects, engineers, lawyers, and members of NGOs participated in the municipal planning process (World Bank 2012).

Along the Rias coast the response of the majority is that the government has already decided so they can't do anything. Some even admire the massive colossal infrastructure. But the younger generation, in their forties, is opposed to large embankments and tall sea-walls, but they are not the decision makers. In Japanese community associations, it is elderly men who make the decisions. In Ohyakaigan near Kesennuma the community association meets twice a month and tries to involve children as well as older people. The plan is to collectively relocate the 120 households and to have the land cleared by 2015–2016. The

Japanese Institute of Architects (AIJ) is considering using this as a model of participation. Unfortunately people cannot wait and they are now down to 100 households and the community may fall apart because of the delay. The group decided they would not oppose the proposed embankment but suggested it be moved back. Initially the city was not happy but changed their minds after receiving the petition. The proposed municipal plan is now for a much lower embankment further back, but this needs cooperation between the Ministry of Forestry, Japan railways, the National Highways Agency, and the prefecture.

In Kesennuma the citizens' committee oppose the planned harbor embankment, and they are in talks with the municipality and prefectural government. The majority of residents are against the proposal and it is not settled yet. Planning arrangements cannot proceed while there is a dispute, but city officials are making land-use plans assuming the embankment will go ahead. Because there has been so much opposition, a new deadline has been set for October 2013. In other places plans are proceeding more rapidly.

In Kamaishi the three community workers for the prefecture explained that local authorities have to accept what citizens want. Ideally they would simulate different heights of embankment since communities in some places have opposed the plans. If people want something outside, the government's recommended solution planners have to be careful that safety measures are in place and that the community has collectively relocated.

Partly because of citizen opposition, reconstruction of sea embankments, which suffered extensive damage, has been considerably delayed. Local governments in devastated areas cannot decide on the details of restoration plans, as discussions continue on whether to prohibit people from returning to coastal areas. Reconstruction work has started on only 31 % of destroyed embankments. According to the Fisheries Agency, which has jurisdiction over sea embankments, the design of embankments will depend on whether people will live nearby (Daily Yomiuri 2013).

Earthquakes and Their Socio-economic Consequences,

Fig. 14 Photograph of the moment the tsunami inundated the Natori plains by the Sendai Airport on the March 11, 2011 (Credit AP)

E

Local governments were tasked with recovery by the National Government who asked them to develop local plans based on consultation. The problem is they lack the technical capacity, especially in effective methods of involving citizens in strategic decision making. Voluntarily urban planners and architects from all over Japan surged to provide missing capacity. Local government has lots of problems with consultation, which is time-consuming. And it is not easy to convince communities to relocate. Local governments want to consolidate communities to make it more efficient and economical to deliver services, but many of these places were in decline before the tsunami. The fundamental problem is that the authorities do not really know what size population they are reconstructing for. They have to provide facilities to each community, so the cost is enormously considerable (Bhatia et al 2013).

Politics and the Media

There was inevitably a great deal of media attention surrounding the Great East Japan earthquake, especially over the Fukushima nuclear disaster. In addition to the coverage of the aftermath of the earthquake and tsunami, there was intense attention on how the leaders of the then fragile government would respond to the

disaster. The central government was keen to act fast and one of the first projects completed was the 12 m high seawall along the Natori plains by the Sendai Airport. This structure is twice as high as its maximum height than the previous wall. Figure 14 shows the inundation of the tsunami into the Natori plains by the airport.

Although the need to protect the coast from future risks is clear and the government would argue that it is doing what is right in saving towns that have been here a long time, the public pressure was there to spend as quickly as possible and there was money in the economy to support this. But there was a time limit for people (central and local) to decide on what to do, as the government had set stringent deadlines for spending.

The media has mainly focused their attention on the Fukushima Daiichi nuclear disaster. Following the earthquake, a 15 m tsunami disabled the power supply and cooling of three reactors, causing a nuclear accident. All three cores melted in the first 3 days and the accident was rated seven on the INES scale, due to high radioactive releases over following 3 days. Eventually four of the six reactors had failed. The days and months after the failure, the handling of the disaster by the government and TEPCO, the Tokyo Electric Power Company, was under heavy

scrutiny. To this day there is mistrust of the statements made by TEPCO on the safety of the surrounding areas, and some residents in and around the region have instead chosen to self-evacuate or purchased their own Geiger meters to track the radiation levels.

The disaster changed the national debate over energy policy almost overnight. Japan, a country heavily reliant on nuclear power, due to its own shortage of fossil fuels had by June 2012 shut down all but two of the country's 54 nuclear reactors. This discussion continues and it remains to be seen what the true long-term policies and health effects are from the nuclear accident.

For this devastating event, the socio-economic consequences have had local, national, and global effects and will continue for decades to come, raising the question: which is the biggest disaster – the earthquake (concentrated and powerful), the tsunami (vast area affected), or the radiation release (contamination for centuries)?

Looking to the Future

Earthquakes and their socio-economic consequences will continue to dominate headlines as highlighted in the chapter. The need to consider the severity and long-term impacts of socio-economic factors in earthquake risk reduction and disaster management is therefore crucial. Echoing the recommendations drawn from investigating socio-economic impacts of Iranian earthquakes by Hosseini et al. (2013) includes:

1. Promoting public participation
2. Organizing community-level disaster management groups and systems
3. Developing a natural hazards insurance system
4. Establishment of a catastrophe insurance pool
5. Socio-economic impact assessment for future earthquake scenarios

As one anticipates for a future with the possibility of a “million-death earthquake,” below are some additional recommendations to those listed

above, if initiatives scientists and engineers should focus their efforts on for earthquake mitigation and preparedness.

Understanding Human Behaviors in Emergencies

Risk perception is not a precise science and even with the best of intentions, the way one acts when experiencing an earthquake. In an interview with a survivor of the Great East Japan earthquake and tsunami, he recounted how he knew it was the largest earthquake he had personally ever experienced and that he knew that a large tsunami would follow. However, against every rational and educated decision he could have made to run to higher ground, he chose deliberately to rush to the coast, to where his family was. He survived, but many others including his family did not. This is just one of many similar stories (EEFIT 2014). Understanding the needs and reasoning behind actions after a disaster would help us devise appropriate strategies for mitigation. What physical and social provisions would have changed this man's decision?

Incorporating Socio-economic Impacts in Earthquake Loss Models

To better understand and address earthquake risk in its entirety, one needs to go beyond seismic hazard, exposure, and the vulnerability of the built environment. The socio-economic characteristics of populations exposed to earthquake threats need to be integrated within loss estimation models to an integrated and holistic estimate of risk in an area. A realistic socio-economic impact assessment can be used to examine how an earthquake will change the lives of the current and the future residents of a community. However, it is not easy to quantify the changes in social and economic conditions that will arise from future earthquakes. At present these are done as modelled with reconstruction costs per square meter. The main indicators include changes in demographics, characteristics of the community, potential effects of an earthquake on services and the housing market, changes in employment and income levels, and alterations to the quality of life.

As part of the GEM, there has been an emphasis for the first time to review how one could assess the socio-economic impact of earthquakes in loss estimation. The ambition of GEM is to deliver methods, metrics, and open source software that can be used worldwide to explore the compounded nature of earthquake events where environmental processes blend with factors such as urban growth, marginalization, and poverty to bring about and magnify earthquake impacts. The integration of physical risk with (a) the social characteristics of populations and (b) the susceptibility of people to the adverse impacts of earthquakes leads to an encompassing perspective on global risk assessment which:

- Considers loss and damage as part of a dynamic system, where interactions between natural systems and societal factors redistribute risk before an event and redistribute loss after an event
- Mainstreams socio-economic vulnerability and resilience in policy discussions on earthquake loss and damage
- Evaluates loss and damage, taking social factors into account at different time and space scales
- Uses risk assessments in benchmarking exercises to monitor trends in earthquake risk over time
- Recognizes that both causes and solutions for earthquake loss are found in human-(built) environmental interactions (GEM 2014).

Summary

Recovering from a disaster involves all kinds of development and planning activities – land-use plans, building norms, and transport plans. What is unique in post-disaster situations is that all these activities happen in a compressed period of time. Communities must rebuild as quickly as possible to maintain existing social networks and get the economy back on its feet. But they must also be deliberate in trying to maximize the opportunities disasters provide for improvement.

Disasters in the past are often seen as catalysts for change in the built environment. The urgency of rehousing a large number of people affected by the event mean that funds are diverted and attention is paid to the area in need. Time is compressed and here is an urgency to “get back to normal” – to rebuild livelihoods, clear up the debris, repair the damage, and, among the more farsighted, to “build back better.” A challenge in post-disaster recovery and key to reducing the long-term social and economic consequences of earthquakes is balancing the need for speed and deliberation.

Earthquake losses will continue to rise if the community of practitioners working in the field do not come together and try to mitigate these losses together. Earthquake engineers and scientists have the knowledge to dramatically reduce the number of deaths from earthquakes. Preventable deaths are attributed to damage and collapses of buildings and buildings should not fall down. It is clear that earthquakes can have a significant impact on the social and economic fabric of society, both in the short and the long term. The ability of a society to recover depends very much on the precondition of the affected area but even more so on the immediate decisions and subsequent policies made by the governing authorities. Some would argue that losses mainly rise from political factors, not from a lack of knowledge or inability to apply it. Mitigation is not a priority in the short term, and therefore governments and communities are not necessarily interested in devoting adequate resources to mitigation. Several authors would further argue that corruption is the main contributing factor to losses from earthquakes (Escaleras et al. 2007; Ambraseys and Bilham 2011), and unless we tackle this sensitive issue, there is little hope of mitigating catastrophic losses. This is not disputed here. However, one should and must remain positive to strive for a better understanding of the direct and indirect causes of losses in earthquakes and devise appropriate mitigation strategies for the future, tailoring for local sociodemographics and focusing on the either physical or social interventions, or both. Inaction is not an option.

Agent-based modeling; Computable general equilibrium; Economic impact assessment; Economy; Employment; Gross domestic product; Input–output analysis; Integrated assessment; Loss modeling; Macroeconomic impacts; Market valuation; Microeconomic impacts; Nonmarket valuation; Social accounting matrices; System dynamics

Introduction

People live in earthquake-prone areas. Tectonically active landscapes may have produced greater biodiversity, more food and water, through disturbed drainage patterns and wetland creation. Nevertheless over the last 200 years, global population growth has increasingly placed pressure on human settlements and resulted in the proliferation of urban areas worldwide, many in seismically active zones. The opportunities provided by living close to a seismic area are tempered by the risks of loss and destruction during a seismic event. Attitudes toward seismic risk are informed not only by understanding of the geophysical characteristics underpinning seismic events but also by socioeconomic conditions, such as historical attachment to the area, property ownership, and community connectedness. Although risks of damages to property may be handled on an individual basis through insurance markets, risks of seismic events on a societal level are seldom channeled through formal markets, creating a strong mandate for policy analysis and intervention.

Economic modeling of seismic events is based on a pragmatic anthropocentric view of managing risk and uncertainty. Economic modeling can be undertaken *ex post* (after an event) or *ex ante* (prior to an event). *Ex post* economic modeling is often used to grasp the intensity and extent of disasters, to appraise costs of recovery and reconstruction, and to help build a body of information to assist in future management of seismic risk. *Ex ante* economic modeling is hypothetical and is often used to support planning and decision making, particularly pertaining to land use and infrastructure provision, with an emphasis on mitigating effects of, and creating response strategies for, seismic events. Any economic assessment of a seismic event is only a partial representation of the real world, not a comprehensive replication of the reality.

Types of Impacts Captured by Economic Analyses of Seismic Events

The underlying rationale for applying economic analysis to understand the consequences of seismic events is concern for the well-being of those persons affected or potentially affected. For the most part, economic analysis does not aim to measure changes in well-being directly, but rather changes in the level of activity and assets held within the formal *market*-based economy. Commonly used market-based indicators of well-being include business output or turnover, value added or gross domestic product, capital assets including property values, household income, employment, and consumption of goods and services.

Seismic events may also result in a wide range of *nonmarket* social and environmental impacts. These nonmarket impacts may be both negative and positive. On the one hand, negative impacts may result from loss of life and physical health, psychological problems and stress, destruction of family and social networks, inconvenience, and degradation of ecological systems. On the other hand, seismic mitigation measures put in place

Economic Impact of Seismic Events: Modeling, Table 1 Typology of economic impacts associated with seismic events

		Examples of direct impacts	Examples of higher-order impacts
Market-based analyses	Stocks	Damage to buildings, infrastructure, inventories	Reduced purchases of public assets as finances diverted toward disaster recovery
	Flows	Loss of production by businesses with damaged capital	Loss of production by suppliers and customers of businesses unable to operate Reconstruction diverts resources away from more efficient production activities
Nonmarket analyses	Stocks	Loss of life	Loss of social capital via disruption of social networks and relocation of people
		Loss of physical and mental health	Loss of trust in authorities
		Damage to natural capital	
	Flows	Interruption of ecosystem services Loss of leisure as a result of inconveniences experienced during the event and its recovery	Stress associated with lost incomes and jobs

may lead to positive impacts on well-being by creating a greater sense of security and safety for local residents. These social and environmental impacts may be associated with changes in economic activity, e.g., physical or psychological injuries sustained as a result of a seismic event constitute a loss of human capital which may, in turn, result in a loss of economic production. However, methods based solely on analysis of market outcomes are unlikely to capture the full extent of the effects. In such cases nonmarket valuation techniques may be utilized for impact assessment.

Table 1 provides a typology for the various types of economic impacts associated with seismic events. As with most existing typologies (e.g., Rose (2004) and Hallegatte and Przulski (2010)), Table 1 distinguishes not only between *stock* and *flow* impacts but also between *direct* and *higher-order* impacts. The distinction between stocks and flows is well recognized within economics. A *stock* is a quantity of a system variable that exists at a single point in time, while a *flow* is a movement of materials or information to or from a stock over time. Stock losses associated with seismic events include the physical destruction of houses and other buildings, infrastructure, machinery, inventories, and other physical assets, as well as loss of human capital from deaths, injuries, and relocation.

Flow losses include reduction in the rate of output by businesses, reduction in the quantities of goods and services consumed by households over a given period, or the hours of lost leisure as a result of various inconveniences following a disaster.

Direct economic impacts include damage to buildings, infrastructure, and inventories, loss of production by businesses with damaged capital, loss of life, loss of health, and so on. Such impacts are a direct physical consequence of a seismic event. *Higher-order* impacts of earthquakes are those not provoked by an earthquake itself but by its consequences. Sometimes higher-order impacts are referred to as “secondary” or “indirect” effects; higher order is used here to avoid any confusion with “indirect effects” as used in input–output (IO) analysis (Rose 2004; Okuyama 2007). Regardless of the particular term used, the separation between direct and higher-order impacts is often blurred. Particularly contentious is how business interruptions are classified. On the one hand, business interruption caused directly by damage to capital used in production, e.g., damage to the Sendai fishing fleet during the 2011 Tōhoku earthquake and tsunami, may be considered a higher-order impact. On the other hand, this could be referred to as a direct impact, with the term higher-order reserved for business interruption *not* directly caused by damaged capital. These

would include, for example, a number of car factories in Korea and the United States that experienced shutdowns following the 2011 Tōhoku event because of the disruption in supply of key components. Hallegatte and Przulski (2010) propose that higher-order impacts extend to cover those costs or benefits that span a longer period of time and a larger spatial scale or occur in a different economic sector than the disaster itself. Accordingly, business interruptions are direct losses if caused by damage to buildings, plants, machinery, or critical infrastructure or disruption to employees' availability for work, while losses in production that spread to other firms via backward and/or forward linkages are higher-order impacts.

A further point of distinction in the categorization of earthquake impacts, which is not considered in Table 1, is the separation of costs and benefits that arise from the occurrence, or potential occurrence, of an event itself and those that arise from mitigation measures, e.g., earthquake strengthening of buildings, training of urban search and rescue personnel, and so on.

Market-Based Methods

Up until the 1990s, the economic impacts of earthquakes and other disasters had received relatively little attention within mainstream economics (Okuyama 2007). Subsequently, a plethora of studies extended and modified conventional market-based economic models. IO analysis, for example, has been extensively applied in the assessment of higher-order impacts. Other conventional market-based economic methods used in assessment of seismic events include econometrics, social accounting matrix (SAM), and computable general equilibrium (CGE). With largely the exception of econometrics, the remaining methods have principally focused on determining higher-order impacts. Economic impact assessment undertaken using conventional methods must thus rely on either empirical data, engineering models, or estimation to calculate direct impacts. In recent years there has been growing interest in modeling the

economic impacts associated with seismic events using simulation models that do not originate solely from within the economics discipline. These have included inter alia the use of system dynamics (SD), agent-based models (ABMs), and integrated assessment methodologies.

Engineering-Based Models for Valuing Capital Losses

Studies concerned only with the estimation of flow impacts often require, as a direct modeling input, the assessment of the value of earthquake damages to buildings, infrastructure, stocks, and other physical capital. The value of lost capital is required to determine the likely changes in economic production and the expenditure patterns during recovery and reconstruction. A common approach used to estimate the direct costs from seismic events is the use of susceptibility or damage functions. Such functions describe the relationship between one or more seismic parameters (e.g., ground motion) with damage for a certain type or use of object at risk, which can then be directly correlated to economic losses.

Econometrics

Econometrics focuses on providing an empirical basis to economic relationships, through the use of statistical analysis, for testing economic theory, forecasting, decision making, and ex post evaluation. Although perhaps best known for its use in generating short-term forecasts of the performance of national economies, econometric modeling is widely utilized in both microeconomics and macroeconomics. Econometric modeling is also undertaken in combination with other forms of modeling, particularly for the purposes of parameter estimation, e.g., for CGE, SD, and ABMs.

In the analysis of seismic events, several econometric studies have attempted to understand the determinants of the direct costs (e.g., mortality, capital losses). According to Cavallo and Noy (2009), these studies typically employ a model framework that assumes direct costs are related to some measure(s) of the physical magnitude of the disaster (e.g., ground movement) and variables that capture the "vulnerability" of the region to the

disaster (i.e., susceptibility to the impact of natural hazards). Possible determinants that may increase a country's vulnerability include the level of economic development, population, and various political and institutional conditions.

A number of authors have also investigated the higher-order impacts of earthquake disasters. Many of these studies look at changes in conventional macroeconomic indicators, such as GDP per capita, although there has also been some research at the sector level and to changes in poverty as measured by indicators such as the Human Development Index. Other studies on natural disasters, although not necessarily earthquake specific, have also focused on impacts at the village or household level, including effects on consumption, nutrition, and capital. Macroeconomic studies may be generally separated into those that are interested in short-run (up to several years) and those that consider long-run (at least 5 years, sometimes decades) impacts. Examples of short-run analyses include those authored by Hochrainer (2009) and Jaiswal and Wald (2013), while long-run studies include those produced by Skidmore and Toya (2002) and Crespo Cuaresma et al. (2008). The focus of much of the debate in long-run analyses is on the extent to which natural disasters may contribute toward faster economic growth via the replacement of damaged capital with newer and more productive technologies.

Given the highly variable nature of earthquake events, obtaining sufficient data (time series and cross sectional) upon which to build such models poses a significant challenge. By its very nature, econometric modeling also depends upon the assumption that the underlying causal mechanisms do not change in form, strength, or stochastic properties from the estimation period to the forecasting period or from one cross-sectional sample to another. Econometric models are, however, statistically rigorous and may provide stochastic and forecasting capabilities.

Input–Output Analysis

IO analysis is attributed to Wassily Leontief, the 1973 Nobel Laureate for Economics, who in 1936 published the first IO table for the US

economy (Leontief 1941). Arguably, IO models are the most widely applied tool for assessing higher-order impacts of seismic events. A significant advantage of IO analysis is its ability to capture economic interdependencies within a regional or national economy. In its most basic form, an IO model consists of a system of linear equations, each one describing the distribution of economic goods among industries and final consumers. An IO model is typically used to evaluate the way in which changes in production by one economic industry may, through supply chain linkages, ripple through an economic system. Although mainly concerned with flow impacts, IO models have some potential to capture stock impacts when constructed as a dynamic model.

There are several well-known limitations associated with IO analysis, including linearity, absence of quantity–price interactions, rigid structure with respect to input and import substitutions, and neglect of resource (e.g., capital, labor, and land) constraints. In particular, IO models utilize “technical coefficients,” which describe, for any given industry, the quantity of each type of good or service required per unit of production. Although technical coefficients are relatively stable under normal economic conditions, it may be unrealistic to assume that these will remain constant following a disaster, when an economy is likely to be subject to supply shortages and significant adjustments. A variety of ad hoc extensions and refinements have been put forward to help address IO weaknesses. For example, Cochrane (1997) allows for a more flexible treatment of imports to deal with shortages in local production. Similarly, Hallegatte (2008) adapts the IO framework to incorporate production bottlenecks and changes in production capacity, prices, and labor demand.

Recently, the inoperability IO model (e.g., Haimes et al. 2005) has received significant attention in the context of disaster analysis. In mathematical terms, the evaluation of higher-order impacts within the inoperability IO model is similar to other IO models, except that results may be stipulated in normalized terms, with the point of reference being the as-planned level of production for each economic industry. Inoperability IO

models are commonly used to explain the dynamics that underlie business operation losses. For example, Barker and Santos (2010) explore the role of inventory in muting disruption following an event.

Social Accounting Matrices

SAMs are closely related to IO models – both are typically constructed from a country's System of National Accounts. While the traditional IO model focuses on flows among economic actors involved in production (i.e., industries), a SAM additionally describes the way in which income generated by factors of production (e.g., capital, labor) is allocated among different economic actors (e.g., businesses, households). Secondary distributions of income among actors through, for example, tax payments and government transfers, along with allocation of income to savings, are also included, thus providing a complete picture of the circular flow of income within an economy. SAM-based models thus have the potential to evaluate a greater range of higher-order impacts than an IO model. SAM-based models are however subject to the same limitations as IO models, including the use of rigid technical coefficients.

Computable General Equilibrium

Starting with Leif Johansen's pioneering (1960) multi-sectoral study of economic growth, and aided by rapid advances in computer technology, CGE models have now become a standard part of the toolbox of economists concerned with policy-oriented research. In general terms, a CGE model seeks to simultaneously determine commodity and factor prices within an economic market and the quantities of commodities produced and consumed, subject to budget (e.g., household, government) and resource (e.g., capital, labor, land) constraints. Like IO models, CGE models are typically used to assess flow impacts, for example, changes in economic output, gross domestic product, or household consumption of commodities. Dynamic CGE models also have the potential to track changes in stocks (e.g., capital, labor) over a recovery period. While CGE

models have been identified as promising tools for earthquake and other disaster analysis for some time, the number of actual examples in the literature is still relatively few.

When compared to IO and SAM-based models, CGE models exhibit a number of advantages. Firstly, the modeling framework provides for flexibility in the specification of functions describing the production of each type of commodity, including allowance for substitution between inputs in response to relative changes in price. For example, if a particular good becomes scarce following an event due to damage to local production facilities, a CGE model will allow for industries requiring that good for production to increase purchases of the imported form of that good. Secondly, the framework allows for consumers to alter consumption patterns in response to changes in relative prices of commodities and/or income levels. Despite this generic flexibility, practitioners typically concentrate on specifying production functions with substitution only between factor inputs (i.e., labor and capital), between imported goods and domestic goods, and possibly between some other key inputs (e.g., substitution between energy commodities is often included). Practitioners typically rely on IO tables to specify purchases of intermediate goods.

Whereas IO models are mainly suited to the analysis of demand-side supply chain and some income-related effects, CGE models are also suited to the analysis of supply-side effects (i.e., impacts on customers) and price effects. For example, if half of the capital used in producing a particular type of commodity is damaged during an earthquake, among the impacts considered by a CGE model will be the loss of income for the firms directly impacted by lost production capacity, loss of income for suppliers of directly impacted firms, gains in income for remaining firms supplying the commodity as a result of higher market prices, and gains in income for firms supplying commodities that experience increasing market demand as a result of input substitution. Due to the wide ambit of economic impacts considered, with impacts often occurring in opposite directions (i.e., counterbalancing),

CGE models typically generate smaller estimates of overall impact than IO or SAM-based models.

In terms of limitations, CGE models are constrained to the evaluation of economies at equilibrium. A typical CGE analysis is undertaken by “shocking” an economic system (e.g., adjusting capital stocks to reflect damage and reconstruction) and, in turn, evaluating the change in the system necessary to produce a new equilibrium. While the equilibrium nature of CGE models is not a problem with long-run analysis, it is however a significant shortcoming for short-run analysis following a seismic event, when economies are likely to undergo significant adjustment and exhibit out-of-equilibrium dynamics. Rose and Guha (2004) therefore distinguish different response phases following an event and identify some of the variations in model parameters suitable for evaluation at each phase.

The extensive data requirements for a CGE model present a significant limitation to the more widespread application in earthquake economic impact assessment. In addition to all of the data requirements of a typical IO model, a CGE model requires the input of numerous behavioral functions and substitution parameters. Parameter estimation is also often based on data from historic behavior under business-as-usual conditions, and such behavior may be ill suited to describing behavior following a seismic event. Although some advancements have been made toward refinement of model parameters to better suit disaster analysis (Rose and Liao 2005), the examples of such work are still relatively few.

System Dynamics

SD is a dynamic modeling approach for understanding the behavior of complex systems. Jay Forrester, of the Massachusetts Institute of Technology Sloan School of Management, developed SD in the mid- to late 1950s. Examples of complex systems include the environment, economy, and society. Such systems are characterized by the presence feedback loops and time delays and typically exhibit nonlinear behavior. Feedback loops are classified as either reinforcing (i.e.,

exacerbate dynamics away from an equilibrium) or balancing (i.e., regulate dynamics toward a new equilibrium). At the heart of the SD approach is the modeling of feedback loops through time using causal loop and stocks and flows diagramming.

SD has been used to model the economic impacts associated with disruptions to critical infrastructure. Dauelsberg and Outkin (2005), for example, calculate economic impacts as non-equilibrium events with critical infrastructure interdependencies captured through event propagation. Similarly, Portante et al. (2011) describes *EpFast*, a simulation and impact analysis tool developed at Argonne National Laboratory. *EpFast* is a suite of simulation models which focus on evaluating the vulnerability of energy infrastructure to events. They describe an ex ante application of the model to a high-intensity New Madrid seismic event of the US Eastern Interconnection. Kachali (2013) has further applied SD to study the 2010 and 2011 Canterbury (New Zealand) earthquakes. This work coalesce hazard, recovery, and organization disciplinary fields with primary data collected via surveys, case studies, and interviews of impacted organizations, to depict how systemic interactions within and between economic industries affect recovery post-disaster.

Agent-Based Modeling

Closely aligned with understanding the economic consequences of seismic events as complex systems is the use of ABMs. Thomas Schelling is often attributed with the creation of ABMs in the early 1970s (Schelling 1971). ABMs simulate the actions of autonomous agents with a view to assessing their consequences on the system as a whole. Unlike the conventional economic impact assessment approaches, which typically seek to describe movement from, or to, an economic equilibrium, ABMs capture the dynamic (equilibrium or otherwise) interaction of agents typically across space and through time. It is the emergence of patterns and trends in behavior, either as collectives of agents or for the system as a whole, which is of most interest to agent-based modelers.

The generative ability of ABMs is well suited to simulating the behavior of agents at the time during, immediately after, and in the recovery and reconstruction phases of a seismic event when economies are likely to exhibit out-of-equilibrium dynamics. Miles and Chang (2007), for example, developed an ABM which focuses not only on estimating losses but also on the anticipated recovery trajectories following an event. Specifically, the draw on empirical information from previous disasters, rather than regional economic theory, focused on spatial units or aggregate sectors, to model emergent trajectories of an economy. Their models are calibrated using the 1995 Kobe (Japan) and 1994 Northridge (California, USA) earthquakes. As another example, the US Department of Homeland Security applies a large-scale micro-simulation model, termed N-ABLE™, to capture complex supply chain, critical infrastructure interdependencies, and market dynamics associated with seismic events. N-ABLE™ is used primarily to gain insight into network vulnerabilities, economic security, and continuity.

Integrated Assessment Methods

An emerging area of investigation in the economic consequences of natural hazard events, including seismic events, is the use of integrated assessment methodologies. Such methods typically incorporate critical feedbacks between existing disciplinary models (e.g., scientific, engineering, planning, economics, and so on), thus, broadening the boundaries of investigation. They also tend to be spatially explicit in nature, applying geographical information systems to facilitate data entry and reporting. Feedbacks exist between land use, transport, and economic activity which are salient to understanding how communities recover from seismic events (Cho et al. 2001; Ham et al. 2005). Implicit in integration is the view that local communities, cities, and regions are complex systems requiring a holistic approach to their study. Blanco et al. (2009, p. 206) note a key recovery phase priority “consists of developing

methods to better understand how recovery is influenced by the underlying dynamics of change in the natural, built and human environments, notably including influences of planning (e.g., land use, built form) on disaster risk.”

Nonmarket Methods

Nonmarket valuation techniques are essentially concerned with measuring the extent to which changes brought about by an event either subtract from or add to values experienced by individuals. Nonmarket impacts of seismic events, such as changes to safety and security, environmental systems, human health, and cultural heritage, are often difficult to identify and measure. Nevertheless, nonmarket impacts are an important component of the range of effects resulting from seismic events. Noting that the classifications of nonmarket valuation methods vary between authors, three broad categories of nonmarket valuation techniques are identified:

- *Stated Preference Methods.* These methods utilize surveys or experiments to elicit what would hypothetically be paid for values which are not traded on markets. The most well-known stated preference methods are contingent valuation (CV) and choice modeling (CM). CV uses surveys to elicit the monetary value people are willing to pay to avoid a decrement of some type of nonmarket good or service or the value they are willing to accept in exchange for its deterioration. CM is similar to contingent valuation, except that willingness to pay is elicited from experiments in which respondents are asked to rank preferences for different attributes of nonmarket goods or services. Although CV is the more commonly used method, CM has gained popularity over recent years. In the context of seismic events, CV and CM have mainly been used to help ascertain socially optimum policies for risk reduction. Asgary et al. (2007), for example, apply CV to evaluate the benefits of hypothetical earthquake early warning systems, suggesting that their results

could be used by policymakers and businesses to determine the optimal level of investment in such systems.

- *Revealed Preference Methods.* These methods estimate the value of a nonmarket good or service based on observed behavior toward some closely connected marketed good or service. Among these the travel cost method is frequently used to infer the value of recreation, including experience of cultural heritage sites, based on the costs of travel to these sites. Although seldom employed in seismic-related studies to date, the method has the potential to evaluate nonmarket losses and justify the replacement of public goods and services. Loss in beach recreation value at tourist destinations in Thailand following the 2004 Asian tsunami is, for example, one possible application for the method. Hedonic pricing is concerned with inferring the value of individual attributes of a market commodity. In the context earthquakes, it has been used to ascertain the value people implicitly pay for housing with reduced seismic risk, or the loss in value of housing following changing perceptions of risk, based on information from real estate markets.
- *Cost-Based Valuation Methods.* These methods assume that some set of observed market costs can be used as a proxy for the value of an asset. The cost of illness approach has been utilized to determine expenditures on health care and lost wages from illness as a proxy measure of the physical injuries and psychological trauma of seismic events. Replacement cost or restoration cost methods may also be relevant to the valuation of nonmarket assets following an earthquake. Previous valuations of natural capital have included determining the costs of building infrastructure to perform similar functions. For example, many studies have examined the value of wetlands in improving water quality in terms of replacement costs.

Nonmarket valuation methods are subject to considerable limitations. Only stated preference methods are capable of capturing nonuse (e.g.,

option, bequest, and existence) values. However, these studies can be very difficult to implement and must be carefully designed to avoid biases. Additionally, the “free-rider” problem can create incentives for respondents to misrepresent real preferences. Travel cost and hedonic pricing methods are known to be sensitive to model specification, including choice of functional forms. Cost-based valuation methods are not considered to have a sound basis in welfare theory but nevertheless may be of use when there is limited time and resources available and only approximate estimates are necessary.

Despite the relatively widespread recognition of the opportunities for use of nonmarket techniques in the analysis of natural disasters, the number of actual seismic-related applications is still relatively few. Consequently, the use of “value transfer,” i.e., values estimated in one study applied to a later study, is common among practitioners of nonmarket valuation. Unfortunately, there are few guidelines available upon which to evaluate the appropriateness of value transfer methods.

Research Challenges

The economic impact typology outlined in Table 1, and the preceding description of assessment methodologies, provides a general picture of the approaches currently being employed in assessment of the economic impacts of seismic events. Nevertheless, a number of key challenges remain to be addressed.

Defining Model Scope and Reference Mode

Ultimately, the selection of impacts for assessment, and by corollary the choice of economic method used in evaluation, depends on the purpose of the assessment. As stated above, economic impact modeling is primarily undertaken with a view to maintain or enhance well-being; however, some impacts will be much more relevant to a particular audience than others. Insurance agencies, for example, will be mainly concerned with losses that are potentially insured. Local authorities and governments,

however, are charged with considering wider impacts on employment, poverty and inequity, fiscal balances, and so on. Nevertheless, some impacts that arise following a seismic event may be outside the scope of evaluation.

A further point to note in relation to the setting of model scope is that impact is a relative concept, identified by comparing an actual or a hypothetical trajectory of a disaster, with some kind of counterfactual baseline trajectory or reference model, i.e., that which would have occurred in the absence of the disaster. Either trajectory may include or exclude mitigation measures or response strategies, depending on the purpose of the analysis. Although many economic assessments concentrate on comparing situations before and after an event, this approach is only likely to be valid when considering short-run impacts. Economic systems are complex and constantly evolving over time; thus the longer the length of time for the analysis, the more difficult it is to define an appropriate reference mode, with many different alternatives possible. In a survey of businesses one and a half years after the 1994 Northridge (California, USA) earthquake, for example, one quarter of businesses had failed to recover to the level of operation prior to the event (Tierney 1997). Some of these businesses may, however, have experienced a state of decline even without the event. Similarly, following an event it has also been proposed that new or more productive economic sectors may emerge, assisted by the investment in reconstruction and opportunities to replace capital with newer and more productive capital (e.g., Skidmore and Toya 2002).

Determining Economic Impact Assessment Boundaries

It is very important in undertaken economic impact assessment of seismic events that the boundaries of the study are clearly defined and communicated with intended audiences. Generally speaking, boundary challenges fall into three categories: spatial, temporal, and distributional.

First, the spatial extent of any assessment requires careful consideration if impacts are to be appropriately accounted for locally,

regionally, and nationally. Until the mid-1990s most economic impact studies of seismic events focused mainly on the location directly impacted. Since the early 2000s, with growth in the development of multiregional IO tables and, more recently, spatial CGE models, spatial impacts have increasingly been incorporated in economic impact assessment. A number of studies (e.g., Okuyama 2004, Tatano and Tsuchiya 2008) note that there are often significant economic transfers between regions brought about through the relocation of people, business activity, and recovery operations. While an impacted area may experience significant economic losses in the period immediately following a seismic event, locations a little farther out may experience the opposite. Moreover, there are dynamic higher-order economic feedbacks which exist between regions, for example, competition for labor or capital between an earthquake-damaged area in recovery and an adjoining area experiencing growth. Inappropriate boundary selection can thus easily lead to the unintentional netting out of impacts.

Second, the economic consequences of seismic events are often felt most in the period immediately following an event but nevertheless continue into the recovery period and longer. Seismic events are also often felt as a series rather than as a single event, e.g., the 2010 and 2011 Canterbury (New Zealand) earthquakes. These characteristics change not only economic flows but also stocks, resulting in lags that lead to oscillation in key economic variables through time. The conventional market-based econometric, IO, SAM, and most CGE models require significant adjustments if such time-dependent processes are to be included. Attempts to include temporal dynamics into economic assessment have been made by Okuyama et al. (2004) in the specification of the sequential interindustry model, by Barker and Santos (2010) in the formulation of dynamic inoperability models, and by Rose and Liao's (2005) CGE model. It is worth noting that dynamic analysis is also a key strength of SD and ABM approaches. The temporal analysis of disaster impacts is, as Rose (2004) and Okuyama (2007) point out, still ad

hoc in nature – lacking an underlying theory to support their application.

Finally, a common criticism made of many economic impact assessments is that only aggregate or sector impacts are reported. There is however growing interest in understanding how economic impacts, both direct and higher order, are distributed across businesses and communities. Understanding economic consequences by socioeconomic and demographic variables including household, family, ethnic, and income types is potentially important to identifying socioeconomic vulnerability and, in turn, through mitigation and adaptation, building resilient businesses and communities. It is worth noting that SAMs, CGE, SD, and ABM models, if appropriately configured to include disaggregated household types (or similar), are ideally suited to addressing this challenge. Nevertheless, there is a current dearth of assessments that explicitly address distributional issues.

Building Confidence in Economic Impact Assessment

The validation of an economic impact assessment can only be judged against its intended purpose. Unfortunately, like all models of complex systems, there is no mathematical or absolute proof that an economic impact assessment may fulfill its purpose. Furthermore, we can conclude that any economic impact assessment is inherently imperfect. Like all models, any assessment represents a simplification of reality. It is not so much whether an assessment is valid or not but whether it is useful. Methodological pluralism is required when assessing the economic impacts of seismic events as there is “no one size fits all” assessment method. Nevertheless, confidence may be built in applying methods through the use of sensitivity and uncertainty analysis. Sensitivity analysis is essential for learning how general patterns of behavior exhibited by impact models change in response to key input parameters, narrowing down key drivers of change in a simulation. While sensitivity analysis may be used to identify the key exogenous drivers of change, uncertainty analysis adds value by

investigating model parameters through numerous experiments based on appropriate sampling methods, i.e., Monte Carlo.

Summary

In the context of responding to seismic risk and events, the behaviors of formal economic markets, alone, are unlikely to produce outcomes that are overall in the best interests of communities. Since the 1990s, economic modeling of seismic events, and their associated responses, has risen as an important tool in assisting policymakers in managing risk and adopting appropriate mitigation and response strategies. The application of economic methods to date can be grouped based on whether the assessment is *ex post* or *ex ante* an event and based on market or nonmarket analysis. The range of impacts that may be considered in assessments are vast, from analysis of only direct damages to physical assets to analysis of higher-order upstream and downstream business disruptions, competition for scarce materials during rebuild, and even valuation of destruction of natural capital and psychological trauma. Although conventional IO and econometric models dominated much of the early literature, during the last decade there has been a strong interest in extended IO, SAM, and CGE models. Modeling techniques applied in disciplines outside of economics, particularly SD, ABM, and integrative modeling approaches, are also now being used to assess the economic consequences of seismic events. Although the potential for use of nonmarket valuation techniques is also recognized, to date their uptake has been limited. It is important to note that “no one size fits all” method exists and that all methods are inherently imperfect. In this regard, there are many research challenges still to be addressed.

Introduction

Earthquakes can affect economies and economic activity in a number of ways. Directly, an earthquake can damage assets and infrastructure critical for the production and delivery of goods and services. Earthquakes can also directly affect human capital, impacting the availability and productivity of the workforce. These however are not the only ways in which earthquakes impact an economy; indirect (or secondary) effects of the disaster can magnify the disruption caused by direct damage. Here, we describe the ways in which earthquake disasters can impact an economy, starting with macroeconomic impacts (how the local economy as a whole is affected) and then focusing in on microeconomic impacts (by looking at how different actors within an economy can be affected). We conclude by looking at ways in which economic recovery can be supported following a major disaster.

Macro-impact of Disaster and Recovery

The economic research on the process of recovery in the aftermath of natural disasters is mostly of recent vintage. The typical view of a recovery process is that the initial impact entails

a downturn in economic activity, as much productive capacity and infrastructure are destroyed and supply networks are severed. However, this initial period of difficulty is assumed to be followed by a period of enhanced activity, largely as a result of additional spending on reconstruction of infrastructure and housing.

The increased spending on reconstruction creates additional economic activity as these resources are cycled through personal consumption and investment decisions. The exact magnitude of this post-disaster boom in economic activity depends both on the quantity of the additional spending, the ways in which this spending is financed, and on the magnitude of the multiplier effect (the multiplier is the beneficial feedback loop from current spending that generates income for others, which is then cycled back into the economy as future spending). Thus, a post-disaster wage subsidy, for example, provides additional income to wage workers, who then spend at least some of this additional income on consumption goods (food, hospitality services, durable goods, etc.). The recipients of this additional spending in turn increase their own spending as their incomes increase, and the money keeps being recycled through the local economy.

Once the reconstruction phase is complete, the economy returns to its “normal” state, typically assumed to be the one that would have prevailed had the disaster itself not happened. This view can be traced at least back to Adam Smith’s description, in the *Wealth of Nations*, of the process of recovery in Swiss cantons that experience periodic flooding.

This view was largely unexamined in the economic literature until the last decade. The empirical evidence that has now begun to surface (Cavallo and Noy 2011) includes several empirical regularities that are described in the sections below. Many questions about the precise description of a typical post-disaster recovery, as well as the idiosyncratic and contingent differences between different recoveries, however, remain open.

Some of the regularities are the following: In the immediate aftermath of large disasters, low- and middle-income countries typically experience some slowdown in economic activity, but

the magnitude of the slowdown is only partly a function of the nature of the disaster (e.g., hydrometeorological vs. geophysical), its spatial extent, its magnitude, and its timing (e.g., with relation to the crop cycles). The slowdown is also, maybe mostly, a function of the economic vulnerabilities of the affected region (e.g., the degree and nature of diversification in the economic sectors that dominate the affected region).

In high-income economies, however, even large disasters seem to have very little macroeconomic aggregate effects. Thus, even a megadisaster, such as the triple earthquake-tsunami-nuclear event in Japan in 2011, has had only very temporary impact on the aggregate Japanese economy. In the long run, it appears that disasters have little measureable impact on the national economy (Cavallo et al. 2013).

Impacts on prices are not well documented. The scant evidence that is available appears to suggest that goods and services that are directly required for the reconstruction efforts seem to experience price increases as a consequence of increased demand and limited supply. Most typical is an increase in the cost of construction and construction workers' wages. These increases do not seem, however, to translate into more general price increases unless the event itself generated specific bottlenecks and supply constraints, e.g., the destruction of oil refineries in the Gulf of Mexico during hurricane Katrina of 2005.

Fiscal Impacts of Disasters

The fiscal patterns are clearer, and maybe more obvious. Disasters generally entail an increase in spending and a decrease in tax revenue, as some of the new reconstruction spending is paid for by the public sector, and the supply bottlenecks and destruction of productive capital reduce economic activity, and hence taxable income. As already noted, the decline in aggregate economic activity is temporary, and thus the observed decline in tax revenue also does not endure unless tax rates are different across economic activities or the disaster itself leads to significant shifts in tax policy.

Public spending on reconstruction, in contrast, can endure as the duration of the reconstruction efforts can last for more than a decade. Thus, the observed increase in the budget deficit, and the consequent increase in government borrowing, is largely due to increased spending rather than decreased revenue.

This picture, however, does not describe accurately the ways in which very poor countries have to conduct their fiscal policy in the aftermath of a catastrophic disaster. Low-income countries have less access to credit markets; and their high cost of borrowing and their narrow tax base prohibit them from spending adequately on reconstruction. Yet, even in these cases when the government is not able to spend on an aggressive recovery effort, this failure does not necessarily imply reduced public sector deficits as spending does not increase. In these cases, the inability to spend on recovery implies that incomes do not recover, and the tax revenue is decreased. This is frequently compounded by the fact that in poor countries, much tax revenue comes from taxes on imports, and imports typically decline precipitously when incomes are significantly decreased. Thus, in both high- and low-income countries, earthquakes will entail increasing government budget deficits. It is only in rare cases, when, for example, much of the damage was privately insured or reinsured internationally that the government finances may not suffer much (e.g., Doyle and Noy *in press*).

Consumption and Trade

Since government spending and public and private investment will tend to increase in the aftermath of large disasters, consumption and/or the trade balance has to decrease (as the sum of these four components is equivalent to national income in the national income accounts). Both of these declines are well documented.

Research that has examined household spending patterns in post-disaster environments generally concludes that one can observe decreases in spending that are more concentrated in poorer households and that the decrease

in spending frequently is concentrated in luxury goods (less surprising) and health and education (clearly more worrying as this decrease may entail long-term adverse consequences). This pattern is not unique to low-income countries but is also documented, for example, for households in the Japanese city of Kobe after the 1995 earthquake (Sawada and Shimizutani 2008).

For trade, it is not unusual to observe declines in imports, and especially in imported luxury goods, but these are typically offset by increases in importing of building materials, fuels, and other goods associated with the reconstruction effort. After an initial decline in exports, as the productive capacity of the affected region is damaged, the overall and longer-term impact of a typical earthquake shock on exports is largely contingent on the types of exports the country specializes in and the nature of the earthquake damage to production facilities, transportation infrastructure, etc. In some cases, one can potentially observe a counterintuitive increase in exports, especially if the earthquake disaster led to a depreciation of the currency, making exported goods more affordable for foreign buyers.

While predicting the typical impact of an earthquake on exports of goods is fraught with uncertainty, exports of services are almost always harmed by a disaster. Especially vulnerable is the tourism sector, as the tourist trade is mostly dependent on image branding and perception rather than on the actual capacity to supply services. Thus, tourism declined significantly in places where earthquake damages occurred in tourist areas (Sri Lanka and Southern Thailand in 2004 or Japan, Chile, and New Zealand in 2011).

Regional/Local Economic Impacts of Disasters

While the aggregate impact of disasters at the national level may be muted, as productive capacity and labor are able to relocate away from the disaster-affected areas, the impact of the event locally may be felt quite differently.

The limited evidence seems to suggest potentially very long-term adverse impacts at the local level that are quite distinct from the relatively benign impacts at the national level, even for fairly short horizons. At the very extreme, some regions never recover at all from a large event. Such an extreme example is the island of Kefalonia, in which a devastating earthquake in 1953 led to mass exodus from the island, and the population on the island was permanently reduced by more than 20 %. While such an extreme case is unusual, earthquakes and other geophysical events can lead to a redistribution of population and economic activity that may persist for long periods of time.

The exact nature of the long-term impact of an earthquake on the regional/local economy depends on the structure of the economy of the region. For example, the agricultural sector is relatively resilient to earthquakes, and even if the earthquake damages some of the processing and transportation infrastructure, this can be quickly rebuilt. Other sectors may be more vulnerable, especially if these were already facing difficulty before the event. In the city of Kobe, for example, the heavy industry of the region was already facing increasing competition from elsewhere in Asia (in particular from China) before the 1995 earthquake. The earthquake itself led to a speeding up of a process that would have potentially occurred even without the earthquake. Much of the heavy industry was not rebuilt and reopened in Kobe in the years after the quake, in spite of massive government assistance for the region.

Paying for Reconstruction

The ways in which post-disaster reconstruction is financed is an important aspect of the recovery process. In general, public infrastructure investment during the reconstruction effort can be financed by: government borrowing (debt financing), government printing of money (the so-called seigniorage tax: the profits the government received from printing money and then using it), international aid, and insurance

Economic Recovery Following Earthquakes Disasters, Table 1 Earthquake losses insured by country for some recent earthquakes (Source: Swiss Re sigma catastrophe database)

Date	Country	Losses	% GDP	Insured losses %
April 2009	Italy	\$4B	0.2	14
January 2010	Haiti	\$8B	121	1
February 2010	Chile	\$30B	18	27
April 2010	Mexico	\$0.95	0.1	21
September 2010	New Zealand	\$6B	5.3	81
February 2011	New Zealand	\$15B	10	80
March 2011	Japan	\$300B	5.4	17
October 2011	Turkey	\$0.75B	0.1	4

(explicit insurance, insurance-like financial instruments such as CAT bonds, or more informal insurance arrangements). Some of these channels may be more efficient and lead to more equitable distribution of resources than others. It is also quite difficult to assess the need before an event and the implementations after an event of these different funding strategies, as government spending on recovery efforts is typically only a small part of overall government spending, and the coincidental benefits and drawbacks of this funding are difficult to attribute.

In recent decades, governments rely less on seigniorage as a means of paying for a post-earthquake reconstruction and appear to favor borrowing. International aid is typically not that large, even after very catastrophic events, and in many cases much of it is not channeled through the government (e.g., Katz 2013).

Investment by the private sector, and in particular business investment, can be financed by insurance receipts but also by previously accumulated savings, by remittances received from abroad, or through borrowing on international or domestic capital markets. The ability of businesses to recover from the initial destruction associated with the earthquake is, in addition to other things, partly a function of its ability to invest in reconstruction and may also be a function of the type of financing available. Yet, our knowledge of any general conclusions about this process is quite limited – see an exception on post-tsunami Sri Lanka in De Mel et al. (2012).

Households' ability to finance their own recovery is also dependent on the availability of financing. It appears that households that have access to borrowing, or to resources from insurance policies or remittances, are able to recover more quickly and more fully than households whose access to credit is constrained (e.g., Sawada and Shimizutani 2008).

It is worth noting that the degree to which households are insured against earthquake risks differs dramatically across countries. In California, for example, earthquake insurance is bought separately and is very expensive, so that most households are not insured. In contrast, in New Zealand affordable earthquake coverage is part of a standard residential housing insurance policy and is partly handled by a public insurance entity backed by the government (the New Zealand Earthquake Commission). Earthquake risk in New Zealand is thus almost fully insured at the residential level. In most middle- and low-income countries, earthquake insurance policies are either unavailable or prohibitively expensive. See Table 1 showing a comparison for recent earthquake events by country of information collated by Swiss Re. Swiss Re reports financial losses, both insured and uninsured, attributable to the event, including physical property damage, and business interruption as a result of property damage caused by the event. Indirect losses are not included in estimates of total economic losses. Sources for their information comes from newspapers, direct insurance and reinsurance periodicals, specialist publications, and reports from insurers and reinsurers.

Changes in Consumer Behavior

Large natural disasters, including earthquakes, can result in significant shifts in population and changes to consumer behavior, all of which affect the potential for economic recovery.

Large losses of housing can lead to permanent losses of population. Past experience has shown that even when less than 10 % of housing units are lost, the time to repair or rebuild uninhabitable housing units can still be very long (SPUR 2012). In the absence of adequate interim housing, some outmigration is likely, and the loss of population will impact the local economy and overall recovery. Permanent loss of population, and the accompanying social and economic impacts, can occur in communities where housing losses are as low as 5–10 % of the total housing stock (SPUR 2012).

Loss of community facilities (such as access to health-care and education facilities) and disruption to critical infrastructure (such as power, water, sewage, and transportation services) can also trigger certain parts of the population to either temporarily or permanently leave the area. For example, following the Canterbury earthquakes in New Zealand, many pregnant women and people with young children chose to leave the area, many to stay with family and friends in other parts of the country, to get away from the ongoing aftershocks, and to wait for services to be restored.

Population loss however is not an inevitable consequence of disasters, and the incoming workforce to undertake the reconstruction effort can lead to an overall increase in population. The demographic mix of the community however can evolve over this process as the characteristics of the incoming population differ from those who leave.

These rapid changes in both the number and mix of people living in a community have implications for organizations operating within the region, as inevitably the customer base and their needs change. Localized areas of damage or disruption to transportation networks can see marked shifts in where people shop. In any disaster, there are always winners and losers, and

sometimes this can be dictated by simply which part of town an organization is operating from. In a post-disaster environment, organizations need to revisit their business plans to identify what strategies will work in their new environment. For example, organizations may need to shift from in-store to online retailing or from retail to whole-sale operations; they may also need to change their mix of product lines to meet changed customer needs. Adapting to the changed circumstances and finding new ways to thrive in the post-disaster environment is vital for business recovery.

While some sectors are more vulnerable than others to natural disasters, the type of industries that are most affected by a natural disaster depends on the nature of the specific event and the industrial structure of the affected region (Venn 2012). Some particular examples noted by Brown et al. (2013) relating to sector-specific earthquake vulnerabilities include:

- Manufacturing businesses often have specialist machinery and premises making it difficult to find suitable alternative premises in the event of property damage. If specialist machinery is damaged, there may be a long lead time for replacement equipment.
- Tertiary education and tourism sector organizations are reliant on customers from outside the affected areas and can be affected by a perception that the area is no longer a fun or safe place to visit.
- Retail and hospitality can suffer from both drops in visitor numbers and changes in discretionary spending by locals.
- The vulnerability of the agricultural sector is very seasonally dependent, with an earthquake having potentially minimal impact during some times of the year and more severe impacts at others.

In addition, Stevenson et al. (2011) found that businesses located in central business districts or densely populated areas face a greater chance of disruption due to neighborhood effects, with greater potential for access problems due to damage because of greater building densities and/or higher concentrations of historic buildings.

Workforce Issues

Common disaster effects on labor markets include: job and worker displacement, loss of income, and additional participation or entry barriers into the workforce. In addition, labor markets can be fundamentally changed due to restructuring of the economy as a consequence of the disaster itself, or during the reconstruction.

Current understanding of the impact of disasters on labor markets largely relies on indicators of labor market outcomes, such as job losses, labor-force participation, and unemployment. It can be difficult however to distinguish disaster-related effects on the labor market from those of other shocks and developments which occur simultaneously.

In general, natural disasters tend to create large-scale shifts in the demand for skills. This can lead to a paradox of skill shortages coexisting with relatively high unemployment and low rates of labor-force participation. In some cases, there is a marked decline in employment in certain industries while demand for other services, particularly construction, increases. Apart from the sectoral vulnerabilities, women and young people are often most negatively affected. Female workers tend to be badly affected as they are less likely to be able to take advantage of new job opportunities during the reconstruction phase. Time needed for construction training means young people, particularly school leavers, have less chance to take up immediate employment in construction.

The way natural disasters can disrupt labor supply is by displacing people from their normal lives and jobs. Damage to property and infrastructure often force people to evacuate to areas outside the disaster zone. According to Venn (2012), mass evacuations can lead to severe labor market disruptions, making it difficult for evacuees to retain their pre-disaster jobs and putting a strain on local labor markets in the areas to which people have been evacuated.

Businesses are the core medium through which a workforce participates in the labor market. Businesses may be subjected to temporary or permanent closure as they deal with physical damage and loss of customers. Some businesses

will be able to reopen quickly, while others may take much longer or may never be able to reopen.

Family and health issues can have negative impacts on a worker's performance. In a survey of over 300 businesses in the Canterbury region of New Zealand following the September 2010 earthquake, more than a quarter of respondent organizations reported that managing staff well-being in the weeks following the earthquake is the biggest challenge affecting their organizations (Kachali et al. 2012). Heightened emotional strains can be related to other factors such as disruption to childcare arrangements, disruption to public transportation, the slow process of receiving insurance payouts and repair information, and a lack of suitable accommodation while houses are being repaired or rebuilt. While businesses are trying to reopen, relocate, and return to normal, staff may be struggling with personal recovery demands.

Post-disaster labor market indicators show that many of the people who are temporarily displaced from jobs soon find new jobs on their own, either in the same area or elsewhere, but help is needed to manage their transitions back to the labor market. It is a complex undertaking for policy makers, firstly, to identify these groups and individuals and, secondly, to provide the support that is needed to address the barriers to their labor-force participation.

Research looking at workforce policy post-disaster suggests the importance of a multifaceted approach to post-disaster labor market response by combining short-term job creation with longer-term skills development and combining short-term job protection with longer-term economic promotion strategies (Chang-Richard et al. 2013).

Common building blocks of "best practice" identified within APEC economies for managing post-disaster labor markets are shown in the Table 2 below.

Economic Stimulus Effects of Reconstruction

In a post-disaster environment, there is strong pressure to act quickly to get back to normal.

Economic Recovery Following Earthquakes Disasters, Table 2 Principles for natural disasters' sound workforce strategies (Chang-Richard et al. 2013)

Principles	Guidelines
1. Target and tailor measures with flexibility	Employment strategies (e.g., public works, employer subsidies) should be targeted for the most troubled sectors and/or needed groups and individuals; if fiscal capacity is constrained, resources should be directed to sector groups that have the most potential to generate employment
	Social protection measures should be as flexible as possible to meet the needs of beneficiaries, reducing application "red tape," providing easy access, extending the coverage and length of support
2. Institutional and organizational innovation	An overarching recovery strategy with employment being one of key components provides a framework for an efficient, responsive labor market response
	A truly dedicated response team in respective policy domains (regional development organizations, rebuilding advisory services, skills specialist officers) will drive efficiency and higher levels of engagement from the industry and community
	One-stop design is critical to the success and accessibility of employment services
3. A diversity of multiagency collaboration	A diversity of collaboration among multiple agencies is essential to ensure coverage of assistance and combination of capacity (financial, technical, and "know-how") for effective service delivery
	Expertise and "know-how" knowledge of nongovernment organizations, particularly the International Labour Organization (ILO), should be drawn on, promoting a collaborative approach to supporting employment and livelihood assistance
4. A focus on sustainable employment outcome	A commitment to sustainable employment outcomes requires social protection measures to be coupled with training and skills development programs, job creation activities to be combined with productivity and skills enhancement, and disaster labor market response to be integrated in regional workforce development strategies
	Workplace-based employment retention and livelihood support play an important role in overcoming workers' participation barriers
	Self-efficacy and employability concepts should be built into the design of self-employment assistance and training programs, respectively, with a focus on linking support measures with direct employment outcomes
5. Capacity-based preparedness and response	Predesigned labor market response policies which can be quickly activated ensure timeliness and efficiency of employment assistance
	Existing networks and relationships, together with a strong leadership, allow resources and capabilities to be quickly assembled and/or redirected in response to the changing needs over the recovery time
	Fiscal, technical, staffing and technological capacity is essential to ensure efficiency within service delivery
6. Local input and place-based solutions	Economic and business recovery should increase the engagement of local organizations and people with local and industry knowledge
	Employment assistance provided to displaced workers and job seekers, particularly those disadvantaged (youth, women, people with disability, long-term unemployed), can be based on their individual needs and opportunities identified by themselves
7. Robust labor market intelligence	An evidence-based approach, building on what has proved to be good practice in international experience is instrumental in designing a similar measure. Business surveys will allow for more responsive and targeted assistance
	Labor market programs should be based on robust labor-force information which will contribute to a sustainable and resilient employment services system

The need to replace lost homes, infrastructure, and commercial properties generates a surge in demand for reconstruction that can act as a short-term stimulus to the local economy. This stimulus benefits not only the construction sector but also other sectors that directly support the construction sector (such as lawyers and accountants, office-supplies providers, and accommodation providers) as well as those sectors that indirectly benefit from the wages and salaries paid to those working on the rebuild (such as the hospitality sector, retailers, and arts and recreation providers).

While demand surge in the construction market can provide a buffer to an economy affected by disaster, it can also create imbalance and dysfunction. The key characteristic that distinguishes the post-disaster condition from normal times is time compression which requires an unusual pace of capital expenditures and reconstruction (Olshansky et al. 2012). In many circumstances, this leads to shortages in capital (machinery, trucks, diggers, etc.), materials (concrete, steel, timber, etc.), and skills (engineers, builders, plumbers, painters, etc.) (Chang-Richard et al. 2012). Such resourcing bottlenecks can lead to price increases and inflows of large amounts of money, and new players in the construction market can also lead to increases in profiteering, corruption, and fraud.

Business Recovery

Business recovery following an earthquake is a crucial aspect for community recovery. Businesses provide employment, goods and services, as well as social support for their employees and for the community at large by way of gathering places. Key aspects impacting on business recovery include levels of earthquake damage to their own premises and surrounding buildings, whether they have to relocate, disruption to their supply chain, changes in consumer behavior, and the impact of infrastructure disruption (Tierney 1997).

In the immediate aftermath of a damaging earthquake, a business owner may need to make the decision to relocate their business due to

damage or safety cordons that have been put in place. This is a major decision for an organization as it may contribute to employee decisions to stay or leave as well as impacting on customer flows through patterns of foot traffic and agglomeration effects (where similar businesses are colocated thus increasing the customer traffic for all of them). The decision to relocate is a complex decision and is complicated further by such factors as: does the business own, rent, or lease the building; level of damage to the building; damage to the neighboring buildings and the presence of a safety cordon (e.g., Chang et al. 2014) preventing access to the building or to nearby buildings; and availability of infrastructure services.

If the business owns the building, it may have more control over building access, whereas the landlord or the landlord's insurer may prevent a business in rented premises from gaining access. This also applies to speed of repairs, how insurance payouts are used to repair or upgrade the building, and the disruption this has on access to the building. These decisions are typically in the hands of the owner (with some constraints from emergency services and the insurer), while a renter or lessee may find that they have limited influence over such decisions.

Level of damage to the building clearly has implications for the relocation decision. A badly damaged building is a safety and reputational risk to the business and will typically force a closure or relocation. Less obvious however is the situation where the business' building is undamaged but where nearby buildings are badly damaged, closed, and cordoned. In this situation, there is a neighborhood effect in which customer numbers drop significantly as they see the badly damaged neighborhood and assume that all businesses in the area are impacted equally (Chang and Falit-Baiamonte 2002). This situation is particularly difficult for the undamaged business as business interruption insurance is typically dependent on physical damage to trigger a payout. Since they are not physically damaged, there may be no payout, but their cash flow is definitely impacted due to the neighborhood effect.

Availability of infrastructure services such as power, water, and wastewater is a crucial feature for business recovery and the decision to relocate. A building may be undamaged and the business owner desiring to reopen as quickly as possible, but the lack of services may make this impossible. In addition, if infrastructure services are functioning, but at a lower than normal level (e.g., electricity “brownouts” or poor quality water), this may have an impact on ability to conduct business at a competitive quality and undermine the rate of customer return and loyalty to the business.

In the aftermath of an earthquake, it is quite possible that a business and its neighborhood are largely undamaged with full services working. However, there may be significant impacts on their supply chain, both upstream (disrupted suppliers) and downstream (customer impacts and behavior changes). A supermarket may be fine following an earthquake with only minor impacts on their part of town, but their primary supplier’s warehouse may have collapsed and deliveries to the supermarket heavily disrupted, so customers go to other supermarkets and get in the habit of doing so. Even after the supplier can once again deliver reliably (or new suppliers are brought on-stream by the supermarket), customers may be slow to return due to maintained perception and new habits.

Business insurance is a two-edged sword. A swift settlement at expected levels of payout can be a lifesaver to a business, allowing rapid repair or replacement of the building, inventory, and equipment, while also providing much needed cash flow through a business interruption policy. This is a likely scenario if the earthquake damage is not widespread and the business owner has a thorough understanding of their insurance policy and a good relationship with their insurer. Unfortunately these provisos are often not met. Damaging earthquakes tend to be regional in nature resulting in widespread disruption. As a result, there are a large number of claims that the insurers are attempting to deal with at the same time. Insurers become overwhelmed with the consequent workload with the result that settlements are slow in coming, require much

attention from the business owner, and endanger the business further as the owner may focus too much effort on the insurance difficulties and too little on keeping their business running effectively (Brown et al. 2013).

Government Policy Impacts on Economic Recovery

The impact of government policy on economic recovery can be significant. Policies such as national or regional earthquake insurance schemes, direct government loans and grants, employment subsidies, and the establishment of government recovery bodies are all examples of government interventions that can be hugely beneficial or undermine long-term recovery if misguided.

National or regional earthquake insurance schemes can provide much needed capital to an earthquake-hit region following a major event. Examples include the New Zealand EQC (Earthquake Commission), the Japanese JER (Japanese Earthquake Reinsurance) scheme, and the California CEA (California Earthquake Authority). These schemes were all formed through government legislation but vary considerably on how they function. Characteristics that differentiate them include: whether policies cover both residential and commercial buildings, whether policies are mandatory for building owners, the extent to which the government acts as insurer of last resort (it covers further losses once the scheme’s resources are exhausted), and who is responsible for administering the scheme (public or private entities).

An alternative to earthquake insurance schemes is direct government loans and grants following an earthquake. In many countries, earthquake insurance is not available as part of a building owner’s policy and may be unavailable in any form. In countries such as Italy or China, low levels of earthquake insurance are the norm (Asian Development Bank 2008). Where this is the case, a government may still intervene by reconstruction of homes and infrastructure and, much less often, commercial buildings. This

intervention may come in the form of direct government intervention or in the form of grants and loans to the building owners. Such intervention is a form of national self-insurance. This provides the capital to rebuild regionally, while sharing the economic burden with the rest of the country. This risk sharing is of course a characteristic of any insurance scheme, whether explicit or implicit.

Following an earthquake, governments may intervene to support business directly. This may include business recovery loans (such as from the US Small Business Administration) or through employment subsidy schemes (such as the Earthquake Support Subsidy used following the Christchurch earthquakes in New Zealand). The benefit to such government intervention may be the long-term retention of businesses in a region (Hatton et al. 2012). This will typically have a number of positive flow-on effects including higher employment, reduced risk of population dislocation, and generally an increase in the speed of economic recovery. The potential drawbacks to such direct government intervention comes when the intervention is longer term (thus creating a business-government dependency), where investment is inefficient (keeping businesses alive that were on the verge of failing prior to the earthquake, and the government grant/loan simply keeps them alive until the aid runs out), or where the intervention has insufficient accountability resulting in budget blowouts and increased potential for corruption.

In very large events, the national/central government may form a Recovery Authority such as the Canterbury Earthquake Recovery Authority (CERA) in New Zealand following the 2010–2011 earthquakes or the Badan Rehabilitasi dan Rekonstruksi (BRR) in Indonesia following the 2004 earthquake-tsunami in Aceh. Such an intervention provides a central authority to coordinate services, aid, and policy during the difficult recovery period. This will more typically be the case where the event overwhelms local government capabilities or where central government is providing significant direct funding to support the recovery (e.g., in rebuilding housing and critical infrastructure), getting

local government back on its feet, and supporting local social needs. In a few cases, even the central government may be overwhelmed by the reconstruction needs; that was the case in Haiti after the 2010 Port-au-Prince earthquake when the Interim Haiti Recovery Commission led by former US President Bill Clinton was established jointly by the United Nations and the Haitian government.

Metrics of Economic Recovery

How does a city, a region, or a country know they have recovered? What are the ways of measuring the progress from devastation to normality? The complex and multifaceted process of economic recovery has winners and losers, and it has waves of progress and ebbs of disappointment. Metrics that help us to see and measure the progress in population change, consumer spending and economic growth, extent of business relocations, and levels of reconstruction all contribute to the tapestry that is economic recovery.

A key determinant of economic recovery is the state of the population. If there was significant population dislocation and loss, to what extent has the population returned and resettled? If population did not leave, will the population be retained through the difficult recovery period? As noted earlier in this entry, an important feature of population recovery is the employment opportunities available. Other key measures are availability and quality of utilities and amenities (power, water, communications, shopping centers, schools, and higher education) and direct measures of population gain and loss (immigration, emigration, growth of nearby towns, number of working visas issued, etc.). Each of these can be measured and contribute to the complex picture of economic recovery (Table 3).

The condition of a city or region's critical infrastructure is a primary element in economic recovery. Earthquakes are damaging to road, power, water, and telecommunication networks. The recovery of these services can be measured in terms of total level of damage (in physical and monetary terms) and the progress of

Economic Recovery Following Earthquakes Disasters, Table 3 Metrics of economic recovery

Description	Measure
Business birth and death rate	Percentage of total number of businesses
Direct population statistics: immigration, emigration, working visas issued	Number of people and percentage of base population
Levels of employment and unemployment	Total numbers employed and unemployed, workforce participation rates, and percentage of total population of working age
Critical infrastructure reconstruction and recovery	Total km to be repaired, total monetary value of losses, km of repairs now complete, percentage of reconstruction complete in km and dollars. Percentage of rebuild complete
Residential and community building reconstruction	Number of damaged houses, number of houses repaired, demolished, or rebuilt. Percentage of total work completed
Commercial building reconstruction	Number of damaged buildings, number of buildings repaired, demolished, or rebuilt. Percentage of total work completed. Similar but using square meters of floor space rather than number of buildings
Business growth and stability	Total sales in retail and wholesale, sector-specific measures of growth, profitability, and employment
Levels of business relocation	Percentage of businesses in temporary accommodation
Overall measures of economic recovery	Regional GDP trends, total tax take, retail sales, and employment (as noted above)

reconstruction (e.g., number of km of water pipes repaired and percentage of total work completed). Similarly the reconstruction of damaged residential and community buildings (e.g., schools, churches, and other religious buildings) and commercial buildings is important for the economic recovery as well as the flow-on effects to community recovery.

An important measure of economic recovery is the state of business growth, stability, and

profitability. Are levels of temporary relocation still high? Are agglomerations (groups of like businesses such as a fashion district) recovering and regathering? More general economic measures such as levels of exports, total retail sales, and other measures of economic activity round out the broader picture of business recovery. Measures that capture the state of the various economic sectors will also highlight the winners and losers in the aftermath of earthquakes and provide a picture of sectoral recovery that can inform various business and government interventions. For example, tourism and education are export sectors that are often hard hit following earthquake events. Interventions to support the recovery of such sectors (e.g., collaborative international marketing programs) can break the cycle of bad news and accelerate the recovery of such hard-hit sectors.

The growth or shrinkage of an economy can be measured in a multifaceted way to gain a rich picture of general economic recovery. This general economic recovery is dependent on all of the earlier characteristics of population, state of amenities, business stability, and employment and levels of reconstruction. The state of the economy can of course be measured directly as well. Growth of regional GDP, levels of employment, tax revenues, and total retail spending are all useful measures of the state of the overall economy, and the trends on these measures provide a moving picture of the recovery.

Summary

The impact of a large earthquake on a regional economy can be dramatic and complex. It may have devastating short-term regional effects while having limited impact on the national accounts of the country. There are inevitable winners and losers both during the initial response to the disaster and during the long and complex recovery period. The assumed trajectory of recovery: a drop in economic activity in the immediate aftermath of the event followed by a boom during the reconstruction phase may be a reasonable description in relatively richer

countries. However, the picture for local businesses may be far more complex. They must deal with the economic vulnerabilities that existed prior to the quake compounded by the impacts of the disaster, including the need to relocate, loss of key staff, changes in consumer behavior, disruption to their supply chain, and overwhelmed insurers.

In the midst of the challenges faced locally will be opportunities for those able to tap into the changes caused by the disrupted economy including location of consumers, changed demographics, insurance payouts, geographic dislocations, and other changes. Then there is the inevitable reconstruction boom, regardless of whether it is fuelled by insurance payouts, personal savings, or direct government intervention. There will be both disruptions and opportunities. Tracking this unfolding and complex picture is an important feature of economic resilience as policy makers and business owners review the metrics that can warn of troubled economic sectors needing help as well as highlight opportunities for growth.

Introduction

The recent destructive earthquakes that occurred in Japan (2011; e.g., Lay et al. 2013) and New Zealand (2010–2011 earthquake sequence; e.g., Quigley et al. 2012) have clearly pointed out that traditional seismic hazard assessment based only on vibratory ground motion data needs to be integrated with information about the local vulnerability of the territory to earthquake occurrence. Nowadays, a huge amount of information about the characteristics of Earthquake Environmental

Effects (EEEs; i.e., any phenomena generated by a seismic event in the natural environment; Michetti et al. 2004, 2007; Guerrieri et al. 2007) is available for a very large number of earthquakes that occurred not only in the instrumental period and in historical time but also in the prehistorical period (paleoearthquakes, e.g., Mc Calpin 2009; Reicherter et al. 2009). However, available information located in different sources (scientific papers, historical documents, professional reports) can often be difficult to access.

The EEE Catalogue is a free accessible database designed at global level to collect information about the characteristics, size, and spatial distribution of Earthquake Environmental Effects in a standard way from modern, historical, and paleoearthquakes. This database aims to properly retrieve the available information about EEEs at a global level and archive it into a unique database, in order to facilitate its use for seismic hazard purposes. The database implementation has been endorsed by the INQUA TERPRO Project #0811 (“A global catalogue and mapping of earthquake environmental effects”; 2008–2011), through a working group coordinated by ISPRA – Geological Survey of Italy. The first official release of the EEE Catalogue was done under the framework of the XVIII INQUA Congress, held in Bern in July 2011.

The information included in the EEE Catalogue relates to Earthquake Environmental Effects triggered by individual seismic events, classified according to the EEE types considered in the Environmental Seismic Intensity scale ESI-07. For each event, information is collected at three levels of increasing detail: earthquake, locality, and site. Also available imagery documentation (photographs, videos, sketch maps, stratigraphic logs) can be stored in the database. Moreover, within the EEE Catalogue, the epicentral and local intensity values based on the ESI-07 scale are recorded. This allows an objective comparison of earthquake intensity for events that occurred in different areas and/or in different periods.

The quality of the database in terms of completeness, reliability, and location resolution is obviously time dependent and, therefore, is

generally less reliable with increasingly more ancient events. Nevertheless, even where the information is less accurate (historical earthquakes, archeoseismological evidence), the documented effects are typically the most relevant (i.e., most diagnostic for intensity assessment). Similarly, the information from paleoseismic investigations, although poorly representative of the entire scenario, still includes significant data (i.e., local coseismic fault displacements), which are very helpful in estimating a minimum size for the earthquake. At present about one hundred earthquakes are included in the EEE Catalogue.

The implementation of the EEE Catalogue is always in progress through a Web Implementation Interface developed for remote data collection at the following URL: <http://www.eeecatalog.sinanet.apat.it/login>

Earthquake records can be edited only by authorized compilers. Data compilation must be done at three different levels of generalization (earthquake, locality, and site). Moreover, it is currently possible to upload (i) the pattern of coseismic ruptures as linear elements (previously edited as .kml file), at earthquake level; (ii) photographs, sketches, or videos documented a single effect, at site level.

In the next section the structure of the database including mandatory fields at earthquake, locality, and site level is described.

Data can be explored on a public interface (Fig. 1) based on Google Earth; the web page address is available at <http://www.eeecatalog.sinanet.apat.it/terremoti/index.php>

From this URL, it is possible to view (Fig. 2) some general information about the earthquake visible on a Google Balloon, by clicking on the epicenter (yellow star, frame A) including the pattern of coseismic ruptures (primary or secondary), surveyed or interpreted, by clicking on the gray triangle corresponding to rupture zone and activating the box rupture zone (frame B). The geographic distribution of localities (green drops) and sites (classified in 7 EEE categories) can be viewed by clicking on the gray triangle corresponding to locality level and activating the box locality (frame C). By zooming in detail on

each locality and site, it is possible to better locate each individual element (red box in detail in C). Some general information about the locality (e.g., local intensity) and site (e.g., EEE classification, description, reference, and photograph) are visible on a Google Balloon, by clicking on the locality (frame D) and site (frame E). The entire database and photogallery (including maps, video, and other .pdf documents) related to a specific earthquake can be consulted by clicking on the earthquake string in the table of contents (frame F).

The EEE Catalogue is also available on the IAEA-ISSC (International Atomic Energy Agency- International Seismic Safety Centre) portal (<https://issc.iaea.org/home.php>) for use and dissemination within the worldwide nuclear engineering community. To this end, a new database infrastructure has been developed by the adaptation and customization of the EEE Catalogue to the specific IAEA-ISSC standard requirements (e.g., content, reliability, magnitude thresholds, geographic priorities, IPR (intellectual property rights), security policies).

For a quick field survey of EEE data consistent with the EEE Catalogue standards, an application has been developed named “Earthquake Geo Survey” that can be used by IOS and android mobile devices (e.g., smartphones and tablets). Via this application, the user is able to document on-fault and off-fault effects, collect GPS waypoints, and indirectly geo-tag the collected photos. The types of effects that can be reported and described in detail are surface faulting (on-fault effects) and off-fault effects including slope failures, liquefaction, tsunamis, ground cracks, hydrological anomalies, and other effects like trees shaking. For example, regarding the earthquake-induced liquefaction phenomena, the user can select a subtype of liquefaction from a list including the three most characteristic ones (ejection of sandy material, subsidence, and lateral spreading), describe in detail the failure within an extra field, report the maximum diameter of sand boils, select either water or sand ejection, and finally locate the site by activating the GPS and take a photo of the liquefaction manifestation. In addition, the

EEE Catalogue: A Global Database of Earthquake Environmental Effects, Fig. 1 The public interface of the EEE Catalogue, developed on Google Earth. <http://www.eeeecatalogue.sinanet.apat.it/terremoti/index.php>

EEE Catalogue: A Global Database of Earthquake Environmental Effects, Fig. 2 How to explore data into the EEE Catalogue (see text for details)

macroseismic intensity can also be evaluated using the ESI-07 scale and the relevant chart that is provided.

Structure of the EEE Catalogue

The EEE Catalogue is structured at three levels of progressive detail: earthquake, locality and site. Following this structure, the database has been developed using three main tables linked with a one-to-many relation: each record in the earthquake table is associated with one-to-many records in the locality table and each record in locality is associated to one-to-many records in its site table.

A site corresponds to the place where the single EEE of a certain type was observed, for example, a landslide or a ground crack. This is the level at which EEE descriptions (verbal or measured) have to be compiled. As these effects are strongly dependent not only on the amount of shaking but also on many other outer factors, it is possible to assign only an interval of probable intensity values to the effect observed at the site.

Locality includes one-to-many sites and presents a level of generalization, to which intensity can be assigned. It is assumed that at the spatial frame of a locality, random effects associated with the site are removed. Locality can refer to any place: either inhabited or natural. As a natural locality can be a river valley, a mountain slope, a large hill, etc., it is difficult to define exactly the size of a locality: in fact, it has to be small enough to keep separated areas with significantly different site intensities, but large enough to include several sites and consequently to be representative for intensity assessment.

Therefore, the locality has to be defined by expert judgment.

The main table earthquake is intended to present general information on the seismic event, including surface faulting parameters and total area of secondary EEEs. The locality table reports all the information about the characteristics of the locality where one or many coseismic

effects according to traditional macroseismic scales have occurred, i.e., location (coordinates, altitude) and local expression of the earthquake (local macroseismic intensity). In the site table all the characteristics of the site (location, geomorphological environment, etc.) as well as the type of effect (local surface faulting, slope movements, ground cracks, ground settlements, hydrological anomalies, etc.) should be reported.

The list of fields associated with the earthquake table is shown in Fig. 3 (above). Modern and historical earthquakes include the following mandatory fields:

- (a) General data: only year (with estimated age uncertainties $\pm$ and dating method), country, epicentral area, epicentral latitude, and epicentral longitude. Coordinates of the epicenter will be on the fault trace estimated from existing fault-trench analyses. In case the paleoearthquake will be only and/or mainly featured by secondary EEEs, the coordinates of “epicenter” will be coincident with the coordinates of the barycenter of the paleoseismic sites where this event was documented.
- (b) Surface faulting data only if $M > 6.5$: SRL, MaxD, surface faulting type, slip type, and rupture zone (if recorded).
- (c) EEE total distribution: total area of secondary effects (if recorded).
- (d) Seismic parameters: ESI epicentral intensity and estimated moment magnitude (M_w).

At locality level (Fig. 3, below) mandatory fields considered in the EEE Catalogue also are different for modern and historical earthquakes and paleoearthquakes. For modern and historical events, the following mandatory fields are considered: locality name, locality latitude, locality longitude, and ESI local intensity. For paleoearthquakes, the locality level will include off-fault localities recording secondary EEEs.

At site level all the possibilities considered are included in the classification of EEEs indicated in the ESI-07 scale, listed in Fig. 4. For modern and

EEE Catalogue: A Global Database of Earthquake Environmental Effects, Fig. 4 The site table provides a description of the single effect as available in the original source and a first classification according to a standard

terminology (surface faulting, slope movements, ground settlements, ground cracks, hydrological anomalies, anomalous waves, other effects)

historical earthquakes, the following general mandatory fields are considered: site name, type of effects, site latitude, site longitude, EEE description, and reference for description. Then, according to the type of effect, the following fields are highlighted:

- (a) Hydrological anomalies: surface water effects and/or groundwater effects
- (b) Anomalous waves and tsunamis: max wave height, anomalous wave width, and length of affected coast
- (c) Ground cracks: strike, dip, max opening, and length
- (d) Liquefactions: max diameter and max lowering
- (e) Slope movements: type, total volume, and max size of blocks (only for rockfalls)

Where local surface faulting has been observed, strike, dip, type of movement, and local offset (vertical and/or horizontal) are also recorded. For paleoearthquakes, at site level only general fields and fields related to local surface faulting (expected to be found by paleoseismic investigation) must be filled.

Case Studies

The major added value of the EEE Catalogue for seismic risk assessment is the possibility to explore the scenarios of environmental effects

induced by past earthquakes and therefore to identify the areas where the human settlements and infrastructures are more exposed to this hazard. To this end, a high accuracy for the location of EEEs becomes crucial. Typically, EEEs from recent earthquakes are mapped with good accuracy immediately after the event. Nevertheless, even for some historical earthquakes, it is possible to retrieve with very good detail this information (cfr. Serva et al. 2007).

It is the case of the December 28, 1908 (M 7.1), Messina-Reggio Calabria earthquake and consequent tsunamis (Fig. 5), where the EEE Catalogue allows to locate the earthquake/tsunami effects over the present urban texture with a spatial resolution of a few meters, pointing out the areas characterized by the highest risk.

Comerci et al. (2008) have provided a careful review of all available contemporary documents, i.e., technical and photographic reports, newspapers, and other archive material related to the seismic and tsunami event, allowing to recognize and classify a large number (365) of independent environmental effects. These have been categorized as slope movement, ground settlement, ground vertical movement and coastal retreat, liquefaction, ground crack, hydrological anomaly, gas emission, light, and rumble. A large part of the achieved information has allowed to evaluate the epicentral intensity, besides local intensities at 67 sites, by applying the Environmental Seismic Intensity scale ESI 2007.

EEEE Catalogue: A Global Database of Earthquake Environmental Effects, Fig. 5 EEEs induced by the December 28, 1908, Messina Straits, Italy, earthquake in the area of the Messina harbor. If information from contemporary sources is very precise, it is possible to use the EEE Catalogue also for local seismic microzonation

This study has led to the most comprehensive picture of the distribution and characteristics of coseismic environmental effects of that earthquake, a crucial knowledge to better estimate the future impact of a similar earthquake on a region that has seen a broad, and often poorly concerned, urban, and infrastructural development since then.

Furthermore, the EEE Catalogue can reveal possible trends in the spatial distribution of primary and secondary effects. The spatial distribution of EEEs induced by the October 8, 2005, Muzaffarabad, Pakistan, earthquake shows that the location and amount of surface faulting are consistent with the spatial distribution of coseismic slope movements, in terms of both areal density and size (Fig. 6).

Ali et al. (2009) provide a detailed field survey of EEEs in the epicentral area of the Muzaffarabad event. The displacement and surface expression of the causative fault and accompanying secondary environmental effects were observed at a number of places along a capable thrust fault structure (Kashmir Thrust). A complex, clearly segmented, at least 112-km-long surface rupture was mapped with maximum values of vertical displacement on the order of 4–7 m mainly along the central segment of the rupture (52 km between Muzaffarabad and Balakot) associated with maximum slip at depth and a major portion of the energy release. The adjacent segments are instead characterized by scattered minor surface ruptures with a few centimeters of displacement, accompanied by extensive surface cracking, landslides, and severe damage, concentrated in a narrow belt along the fault trace.

A maximum intensity of XI on the Modified Mercalli Intensity (MMI) scale and on the Environmental Seismic Intensity scale (ESI 2007) was recorded in the epicentral area between Muzaffarabad and Balakot. Extremely severe damage and very important secondary environmental effects in the hanging wall adjacent to the trace of the causative fault plane are mainly due to near-fault strong motion and rupture directivity effects.

A similar result is shown by the spatial distribution of EEEs induced by the 1811–1812 New Madrid, Missouri, earthquakes, mapped in Fig. 7. Indeed, the most relevant primary and secondary effects are located along the Mississippi Valley near New Madrid, consistently with the surface projection of the causative faults, and unquestionably provide diagnostic elements for assessing an epicentral intensity equal to XI (Guerrieri et al. 2011).

In the winter of 1811 and 1812, the New Madrid Seismic Zone generated an earthquake sequence that included three very large to great earthquakes. The three largest earthquakes in this sequence are estimated to be of moment magnitude M 7.8–8.1 and were felt as far away as Hartford, Connecticut, Charleston, South Carolina, and New Orleans, Louisiana. In the northern part of the Mississippi embayment, these earthquakes caused widespread liquefaction (Fuller 1912; Saucier 1977; Obermeier 1989) and severe ground failure (Tuttle and Barstow 1996). Liquefaction was reported about 200 km northeast of the New Madrid Seismic Zone in White County, Illinois; 240 km to the north-northwest near St. Louis, Missouri; and 250 km to the south near the mouth of the Arkansas River. Although the exact magnitudes of the earthquakes are debatable, there is no doubt that a repeat of an 1811–1812 New Madrid sequence today would cause a great deal of damage in the central United States (Tuttle 1999).

Future Developments

At June 2014, 101 earthquake records have been collected into the EEE Catalogue: among them, 44 are modern (after 1900), 39 are historical, and 18 are paleoearthquakes. Other 31 earthquake records are currently under implementation. Most of the compiled earthquake records have occurred in Europe (62), then in South America (19), in Asia (16), and in North America (4).

Nevertheless, the compilation of the EEE Catalogue is still ongoing with the aim to collect any available information resulting from

EEE Catalogue: A Global Database of Earthquake Environmental Effects, Fig. 6 Surface faulting and slope movements induced by the October 8, 2005, Muzaffarabad, Pakistan, earthquake

EEE Catalogue: A Global Database of Earthquake Environmental Effects, Fig. 7 EEE induced by the December 16, 1811, New Madrid, Missouri, USA, earthquake. Primary and secondary effects indicative of intensity XI in the ESI 2007 scale are located in the epicentral area along the Mississippi Valley

specific field surveys after recent earthquakes, as well as from historical and paleoseismic studies. For the next future, the goal will be to improve the completeness of the EEE Catalogue with the aim to properly use collected data for an improved assessment of seismic hazard based on a credible scenario of EEEs.

Summary

The EEE Catalogue is a free accessible database (<http://www.eeecatalog.sinanet.apat.it/terremoti/index.php>) designed at global level to collect information about the characteristics, size, and spatial distribution of Earthquake Environmental Effects in a standard way from modern, historical, and paleoearthquakes.

This database has been promoted with the aim to properly retrieve the available information about EEEs at a global level and archive it into a unique database, in order to facilitate their use for seismic hazard purposes. The information included in the EEE Catalogue pertains to Earthquake Environmental Effects triggered by individual seismic events, classified according to the EEE types considered in the Environmental Seismic Intensity scale ESI-07. For each event the information is collected at three levels of increasing detail (earthquake, locality, and site). Also, available imagery documentation (photographs, videos, sketch maps, stratigraphic logs) can be stored in the database. Moreover, within the EEE Catalogue the epicentral and local intensity values based on the ESI-07 scale are recorded. This allows an objective comparison of earthquake intensity for events which occurred in different areas and/or in different periods.

The implementation of the EEE catalogue is always in progress through a Web Implementation Interface developed for remote data collection at the following permanent URL: <http://www.eeecatalog.sinanet.apat.it/login>

The major added value of the EEE Catalogue for seismic risk assessment is the possibility to explore the scenarios of environmental effects induced by past earthquakes and therefore to

identify the areas where the human settlements and infrastructures are more exposed to this source of potential hazard.

Synonyms

MET seismic sensors; Molecular electronic angular and linear seismometers; Molecular electronic transfer seismic sensors

Introduction

Traditionally seismic sensors use a mechanical system with moving solid-state inertial mass in combination with either velocity or displacement transducers. The latter convert mechanical motion of the inertial mass into the electrical signal. An alternative approach based on employment of liquid inertial mass and four-electrode electrochemical transducer with potential difference applied between the electrodes as a converter of the liquid motion into electrical signal was developed in recent years (Huang et al. 2013; Agafonov et al. 2014). Such devices are known as MET (molecular electronic transfer) or electrochemical sensors. Basically, the operation of the MET sensors uses the sensitivity of an interelectrode current in the electrochemical cell to the movement of a liquid electrolyte relative to the electrodes fixed on the sensor housing. Along with the solid-state electronics (charge transfer by electrons and holes in a solid conductor or semiconductor) and vacuum electronics (charge transfer by free electrons in an ionized gas or vacuum), the MET sensors could be considered as the third class of fundamental electronic devices, characterized by charge transfer via ions in solution – hence the older name of the

Electrochemical Seismometers of Linear and Angular Motion, Fig. 1 Schematic of the basic MET sensing element

E

sensing technology “Solion.” Solion technology was first implemented into a practical device in the 1950s by a US Navy-sponsored project. The early applications of Solion devices were to detect low-frequency acoustic waves, either in the form of an infrasonic microphone or limited-band seismometer (Hurd and Lane 1957; Wittenborn 1958; Collins et al. 1964). The first theoretical model describing the physical principles of operation of such devices was developed by C. W. Larcam in 1965 (Larcam 1965) who studied a simple one-dimensional model of four electrodes (two anodes and two cathodes) placed along a channel filled with an electrolyte moving under the action of external inertial forces.

Significant work on Solion motion detectors was continued in Russia, where the term “molecular electronic transfer” was firstly introduced to describe such a device (Lidorenko et al. 1984). Inspired by the exceptionally high rate of mechanical signal conversion to electric current in MET involving mass and charge transport, pioneer studies of MET (Kozlov et al. 1991; Kozlov and Safonov 2003; Panferov and Kharlamov 2001; Reznikova et al. 2001; Agafonov and Krishtop 2004; Volgin et al. 2003) provided an alternative paradigm in the development of seismic sensors. The advantages of MET motion sensors include small size, lack of fragile moving parts, high shock

tolerance, wide operating frequency range, high sensitivity, and low noise, as well as low dependence or complete independence of the response on installation angle. These features are widely used in practice especially in field and ocean-bottom applications, giving important benefits in using a relatively non-expensive, easy to install, compact and at the same time sensitive and low-noise device.

The main part of the current paper includes the following divisions: operating principles, description of the method, how the transfer function is built, and examples of technical parameters for a commercial MET, including velocimeters, seismic accelerometers, and unique highly sensitive compact rotational seismometers.

Molecular Electronic Transducer: Principle of Operation

Figure 1 illustrates the basic concept of a MET sensing element, consisting of two transforming electrochemical cells (Lidorenko et al. 1984). Four electrodes configured as anode–cathode–cathode–anode (ACCA), separated by dielectric spacers, which protect adjacent electrodes from contact, span the channels filled with an electrolyte containing iodide ions. Holes through the electrodes and dielectric spacers allow fluid to flow through the channels.

The sensing mechanism of the MET is based on reversible chemical reactions transferring charge between anode and cathode via the electrolyte ions in the solution (Sun and Agafonov 2010). A solution with a high concentration of a neutral electrolyte (taking no participation in the electrode reactions) and a small fraction of the active component that is responsible for the charge transport over the fluid–electrode metal interface is usually used.

Most of the practical devices use iodine–iodide electrochemical systems with platinum electrodes. The electrolyte consists of a high-concentration aqueous solution of potassium iodide KI (lower temperature range boundary at $-15\text{ }^{\circ}\text{C}$) or lithium iodide LiI (lower temperature range boundary at $-55\text{ }^{\circ}\text{C}$) as neutral electrolyte and a small quantity of molecular iodine I_2 . If there is an excess supply of iodide, iodine enters a freely soluble complex compound (triiodide) according to the following scheme:

When the current flows through the MET, the following electrochemical reactions proceed at the electrodes: the reduction of iodine at the cathode

and the oxidation of iodine at the anode

K and Li ions do not participate in the reactions.

The sensing element operation is based on the fact that rates of the electrochemical reaction at the electrodes are significantly higher than the reactant supply rate. The electrode reactions in this case lead to the emergence of a reactant concentration gradient. Figure 2a shows the distribution of I_3^- and I^- in the stationary electrolyte. Because of the electrode reactions, triiodide concentration maximizes at the anodes and minimizes at the cathodes, while iodide concentration maximizes at the cathodes and minimizes at the anodes. Since the ion concentrations shown in

Fig. 2a are symmetric about the central plane of the cell at $x = 250\text{ }\mu\text{m}$, left and right parts of the sensing element are equivalent, and there is no electric current difference between the two pairs of electrodes.

The ion distributions in the moving fluid are shown in Fig. 2b. From Fig. 2b, the maximum of the triiodide concentration is found at the upstream anode, while the minimum is at the downstream cathode. For iodide, as shown in Fig. 2b, the maximum concentration occurs at the upstream cathode, while the minimum concentration is found at the upstream anode. The maximums and minimums found in Fig. 2b are due to the fact that the triiodide generated at the upstream anode is consumed at the downstream cathode. By comparing Fig. 2a, b, it is found that both the maximum and the minimum concentrations of triiodide are greater when the fluid flows; for iodide the maximum concentration is greater when the fluid flows, while the minimum is greater in the stationary electrolyte. In turn, changes in the ion distribution result in the changes of the electrode current. Specifically, increase of the triiodide concentration in the vicinity of a cathode means acceleration of the electrochemical reaction according to Eq. 2. Inversely, decrease of the triiodide concentration results in the deceleration of the same reaction. So there is a difference between electrical currents for the two electrode pairs in the moving electrolyte. Usually the difference between cathode currents is used as an output signal of the transducer.

As the interelectrode potential difference is increased, the rate of electrochemical reactions increases gradually until such a condition occurs that all the triiodide ions reaching the electrode enter the electrochemical reaction instantly. This condition corresponds to the saturation current regime, and further increase in the potential difference does not alter the current. Under this condition the conversion coefficient of the sensing cell achieves its maximum value. That is why the saturation regime is typically used as a working point for the transducer. The current is limited by the volume rate of supply of the active component to the electrodes. In turn, the supply

Electrochemical Seismometers of Linear and Angular Motion, Fig. 2 Schematic diagram of a four-electrode conduit (the electrodes are denoted by the shaded portions) and ion distributions in (a) stationary

and (b) moving electrolyte. Both in (a) and (b), I_3^- concentration is shown on the upper graph, I^- on the lower one

rate is determined by the ion diffusion in the stationary electrolyte. The flow of the solution introduces an additional convective ion transport that changes the saturation current at each pair of electrodes (see the volt–ampere characteristics (VACs) of the electrode system in the stationary and flowing electrolyte shown in Fig. 3). The convective flow is directed from cathode to anode for the first pair of electrodes and in opposite direction for the second one. That's why changes of the concentration are not symmetrical, and cathode current difference (output signal) is generated.

In the general case, the process is characterized by a high conversion factor. This is reflected in a strong electric response that exceeds the noise of accompanying electronic circuitry significantly, even when the input mechanical influence level is low. A high signal-to-noise ratio is ultimately achieved throughout the entire measurement channel. Numerous experimental and theoretical studies revealed a considerable dependence of the output parameters of the device on the conversion system geometry and the broad possibilities for optimizing the conversion system response depending on the problems being solved.

Electrochemical Seismometers of Linear and Angular Motion, Fig. 3 VACs of the transducer electrode system in a stationary electrolyte (1) and in an electrolyte flowing from the anode to the cathode (2) and cathode to anode (3)

Electrochemical Seismometers of Linear and Angular Motion, Fig. 4 Schematic of different type of MET motion sensor

Motion sensors based on MET technology include linear and angular accelerometers, rate sensors, gyroscopes, and seismometers. MET sensors can be configured for horizontal, vertical, and rotational sensing, as shown in Fig. 4. Despite of the difference in construction, all of them can be described in common rules-based approach. A vertical-axis sensor is considered in the following as an example.

Transfer Function of the MET Seismometers

A MET motion sensor can be considered as a superposition of two systems: first, input motion is converted into fluid motion of the electrolyte by a mechanical system. Next, the electrolyte's velocity is measured by the electrochemical system, resulting in an output current of the sensor.

Therefore, the frequency-dependent transfer function of the entire device can be written as:

$$H(\omega) = H_{\text{mech}}(\omega)H_{\text{ec}}(\omega), \quad (4)$$

where $H_{\text{mech}}(\omega)$ describes the mechanical response of the fluidic system and $H_{\text{ec}}(\omega)$ is the electrochemical transfer function describing the conversion of the fluid flow into an output current.

Considering the design of the vertical sensor (Fig. 4a) in addition to the sensing element, the highly flexible rubber membranes are assembled at the two ends of the channel to seal the electrolyte, providing a restoring force for the mechanical system. In the presence of an external ground acceleration, an inertial driving force is applied on the liquid electrolyte. The electrolyte moves along the channel once the driving force exceeds the hydrodynamic drag force. Let $x(t)$ be the

displacement of the liquid inertial mass m relative to the ground. There are two real forces acting on the liquid mass:

Restoring force from the flexible membrane, $-kV(t)$, is negative since it opposes the flow motion, where $V(t)$ is the volume of fluid passing through the channel and k is the flexibility coefficient of the membrane and depends only on the characteristics of the membrane.

Hydrodynamic damping force, $-\frac{R_h S_{ch} dV(t)}{dt}$, is linearly proportional to the volumetric flow rate of the liquid associated with the hydrodynamic resistance R_h and is negative since it also opposes the flow motion; S_{ch} is the cross-section area of the channel. In this consideration we suppose the cross-section area is constant.

The acceleration of the mass relative to an inertial reference frame will be the sum of the acceleration $\frac{d^2 x(t)}{dt^2}$ with respect to the ground and the ground acceleration $a(t)$. The center of mass acceleration is assumed equal to average liquid acceleration in the channel. Since the sum of forces must be equal to the mass times the acceleration, the equation that governs the motion of the liquid can therefore be expressed as

$$-R_h S_{ch} \frac{dV(t)}{dt} - kV(t) = m \frac{d^2 x(t)}{dt^2} + ma(t). \quad (5)$$

Given the relations:

$$V(t) = S_{ch} x(t), \quad m = \rho L S_{ch}, \quad (6)$$

where m is the mass of the electrolyte, ρ is the density of the electrolyte, and L represents the channel length, Eq. 5 is transformed to

$$\frac{d^2 V(t)}{dt^2} + \frac{R_h S_{ch}}{\rho L} \frac{dV(t)}{dt} + \frac{k}{\rho L} V(t) = -S_{ch} a(t). \quad (7)$$

By changing the variable of $Q(t) = \frac{dV(t)}{dt}$, where $Q(t)$ is the volumetric flow rate, and transforming Eq. 7 to frequency domain, the magnitude of the transfer function of mechanical system in MET transducer in the frequency domain can be obtained as follows:

$$|H_{mech}(\omega)| = \left| \frac{Q(\omega)}{a(\omega)} \right| = \frac{\rho L}{\sqrt{\left(\frac{\rho L}{S_{ch}} \right)^2 \frac{(\omega^2 - \omega_0^2)}{\omega^2} + R_h^2}}, \quad (8)$$

where $\omega_0 = \sqrt{\frac{k}{\rho L}}$ is the mechanical resonance frequency of the device.

An approximation of the electrochemical transfer function in frequency domain is

$$|H_{ec}(\omega)| = \frac{1}{\sqrt{1 + \left(\frac{\omega}{\omega_D} \right)^2}}, \quad (9)$$

where $\omega_D = \frac{D}{d^2}$ is the diffusion frequency and d is the interelectrode distance (Kozlov et al. 1991).

The overall frequency-dependent transfer function of a MET seismometer is a superposition of the transfer functions of the mechanical and electrochemical system, which can be written as:

$$|H(\omega)| = \frac{\rho L}{\sqrt{\left(\frac{\rho L}{S_{ch}} \right)^2 \frac{(\omega^2 - \omega_0^2)}{\omega^2} + R_h^2}} \cdot \frac{1}{\sqrt{1 + \left(\frac{\omega}{\omega_D} \right)^2}}. \quad (10)$$

Figure 5 illustrates the typical response of a MET sensor to the applied acceleration (blue) and velocity (red). Both plots have marked maximums in sensitivity and do not have any flat region. To produce the flat response in the operating frequency range, a procedure of frequency equalization is required.

Two main approaches to equalize the frequency response of a MET sensor have been developed so far:

1. Equalization with a combination of low-pass and high-pass filters (filter equalization)
2. The use of force feedback (feedback equalization)

The filter equalization was used in earlier MET seismometers. The actual parameters of a specific sensing cell are difficult to predict and

Electrochemical Seismometers of Linear and Angular Motion, Fig. 5 Responses of a typical MET transducer to applied acceleration (*blue*) and velocity (*red*). Units on vertical axis are $\mu\text{A}/\text{m}/\text{s}^2$ and $\mu\text{A}/\text{m}/\text{s}$ for the *blue* and *red* curves, correspondingly

Electrochemical Seismometers of Linear and Angular Motion, Fig. 6 Functional diagram of a seismometer with the filter equalization

display a noticeable spread, so the task of achieving the desired accuracy can only be performed by means of the measuring the cell's transfer function directly. Shake tables of various types are necessary equipment to implement this procedure.

The approach is based on the directly measured response of a particular sensing cell in the frequency range of interest and adjustment of the corrective filters to get the desired response in the specified operating frequency band.

Figure 6 presents the functional diagram for the seismometer where the transfer function was built using the filter equalization procedure. Mathematically, the transfer function of a seismometer $H_{\text{dev}}(\omega)$ is presented as a product of the transfer function of the transducer by the transfer functions of the successive electronic filters:

$$H_{\text{dev}}(\omega) = H_{\text{sens}}(\omega) \cdot H_{\text{corr}}(\omega) \cdot H_{\text{out}}(\omega). \quad (11)$$

The adjustment procedure is the following: First the seismometer transfer function is determined by measuring the seismometer response with some initial parameters of the correcting circuit. After that, the transducer transfer function is calculated by dividing the seismometer transfer function by a product of the electronic filter transfer functions:

$$H_{\text{sens}}(\omega) = \frac{H_{\text{dev}}(\omega)}{H_{\text{corr, initial}}(\omega) \cdot H_{\text{out}}(\omega)}. \quad (12)$$

After that the parameters of the correcting filters are remade using adjustable electronic parts. The mathematical modeling is used to find the required modifications. The result of the

Electrochemical Seismometers of Linear and Angular Motion, Fig. 7 (a) Transfer function $H_{\text{sens}}(\omega)$ of a horizontal MET transducer, (b) product of the transfer

functions $H_{\text{corr}}(\omega) \cdot H_{\text{out}}(\omega)$ of equalization filters, (c) resulting transfer function $H_{\text{dev}}(\omega)$ of a horizontal MET seismometer

correction is checked on the shake table. If necessary, the adjustment procedure is repeated successively until the measured response function $H_{\text{dev}}(\omega)$ meets the standard curve within a tolerance predetermined as acceptable. The iterative adjustment process eliminates the influence of natural spread of electronic component values. The equalization procedure and the final result of the adjustment are illustrated on Fig. 7a–d, where real data are used as an example. The amplitude vs. frequency characteristics are shown, where Fig. 7a is the measured transfer function to applied velocity of the transducer, Fig. 7b is the transfer function for the electronic filters, Fig. 7c is the final amplitude vs. frequency curve, and Fig. 7d is the final phase vs. frequency curve for the seismometer.

The accuracy of the filter equalization procedure is limited by the tolerance of the electronic components and the accuracy of the shake table used to determine the transfer function. The usual variation in the transfer function for a broadband seismometer with filter equalization stays

within ± 1 dB for sensitivity and $\pm 30^\circ$ in the passband. What's more, the filter equalization is unable to correct any changes in the transducer's transfer function that may occur in the long term after the factory adjustment. Now this type of equalization is used only in a few models of electrochemical seismometers.

More precise devices use the feedback design. The commonly used technique for a practical feedback implementation is a moving coil system. The flexible membrane (see Fig. 4a) is equipped with a coil placed in a magnetic field of a firmly installed strong magnet. Applying a current into the coil gives rise to a force acting on the moving liquid inside the sensor. Usually, negative feedback is implemented, so that the force produced by the coil acts oppositely to the inertial force. It is important to note that for this approach, due to the high original conversion coefficient of the transducer, the decrease in the conversion factor due to the negative feedback, practically, does not affect the instrument resolution.

The block diagram of the seismometer equipped with a feedback mechanism is presented in Fig. 8, where $H_{\text{corr}}(\omega)$ represents the transfer function of filters and amplifiers in direct circuit, $H_{\text{fb}}(\omega)$ is the same of the feedback circuit, and $H_{\text{out}}(\omega)$ is the transfer function of the output filter.

The most important feature of a feedback is that, provided the system remains stable and the amount of feedback is sufficient, the output function $H_{\text{dev}}(\omega)$ depends mostly on the feedback transfer function $H_{\text{fb}}(\omega) \cdot H_{\text{coil}}(\omega)$ rather than on the transducer transfer function $H_{\text{sens}}(\omega) \cdot H_{\text{corr}}(\omega)$.

Indeed

$$H_{\text{dev}}(\omega) = \frac{H_{\text{sens}}(\omega) \cdot H_{\text{corr}}(\omega)}{1 + H_{\text{sens}}(\omega) \cdot H_{\text{corr}}(\omega) \cdot H_{\text{fb}}(\omega) \cdot H_{\text{coil}}(\omega)} H_{\text{out}}(\omega). \quad (13)$$

In case the amplification inside the closed-loop system is much higher than 1 in absolute value $|H_{\text{sens}}(\omega) \cdot H_{\text{corr}}(\omega) \cdot H_{\text{fb}}(\omega) \cdot H_{\text{coil}}(\omega)| \gg 1$ and Eq. 13 is approximated by the following formula:

$$H_{\text{dev}}(\omega) = \frac{1}{H_{\text{fb}}(\omega) \cdot H_{\text{coil}}(\omega)} H_{\text{out}}(\omega). \quad (14)$$

The feedback circuit results in a counterforce (i.e., a force compensating effect of the acting acceleration) proportional to the current flow. So $H_{\text{coil}}(\omega)$ can be expressed as a function that converts voltage to acceleration.

The practical implementation of the electrochemical seismometer equipped with feedback is:

Task 1: Providing sufficient amplification to have a “deep” feedback

Actually, this is the simplest task among others listed below. First, the transducer itself has a high original conversion factor. Additionally, the electronic industry produces a variety of low-noise operational amplifiers which can be used for additional amplification of a signal.

Task 2: Producing an output proportional to either acceleration or velocity, depending on the instrument type

In case the electronics in the feedback has frequency-independent response, the transfer function of the instrument would be proportional to acceleration. The output filter transfer function $H_{\text{out}}(\omega)$ is used to shape the low- and high-cutoff frequencies.

A velocimeter is more common for broad-band seismometers. In this case, an additional circuit, an integrator as a part of the output filter ($H_{\text{out}}(\omega) \sim \frac{1}{\omega}$ in the passband), or a differentiator at the feedback amplifier ($H_{\text{fb}}(\omega) \sim \omega$ in the passband) should be added (both shown in dashed lines in Fig. 8).

Whenever an integrator or differentiator is used, the transfer function of the instrument would give an output voltage proportional to the ground velocity.

The introduction of an integrator into circuits at lower frequencies is limited by electronic parts leakage and op-amps offset. Also, the substantial variation of capacitors' impedance over the passband in frequency-dependent circuits may impair the noise performance of a device. Therefore special schematic techniques and careful amplifier selection should be made in order to maintain the optimal noise performance of the integrator or differentiator stage.

Another aspect of introducing a differentiator into the feedback circuit is that it brings a leading $\pi/2$ phase shift in the loop amplification. Typically, this phase shift improves feedback stability, and velocimeters with a differentiator in the feedback have better performance at higher frequencies in comparison with devices equipped with an output integrator.

Task 3: Ensuring the stability of the closed-loop system

Maintaining the feedback loop stable is a comparatively sophisticated task.

Electrochemical Seismometers of Linear and Angular Motion, Fig. 8 Block diagram of a closed-loop electrochemical seismometer

Being negative in the middle of the frequency band, the feedback may even change its sign and become positive at some frequency outside the high- or low-frequency band limits due to the phase response variation as a function of frequency. To avoid self-oscillation, it is important to keep the amplification inside the closed-loop system at such a frequency less than 1 in absolute value by all means. This task not only requires considerations of stability when the system is being adjusted, but it's also essential to maintain the closed-loop stable over all temperature ranges and under transitions processes after the device is just powered on or overloaded by a strong input signal.

Changes of an electrochemical seismometer frequency response with variation of the feedback depth are illustrated in Fig. 9. The device response at a low feedback depth is close to the curve of an uncorrected sensor with no visible flat region at all. The deeper the feedback, the wider is the flat region in the device response, but at the same time the lower is the overall sensitivity of the device.

Very strong feedback depth (dark red curve on the Fig. 9) could result in the feedback loop becoming unstable during the transition processes or under variations in temperature.

Most electrochemical seismometers have maximum feedback depth in the range from 10 to 50. The feedback for the electrochemical accelerometers could be as big as few hundred.

Task 4: Sufficiency in feedback dynamic range

For the sake of keeping the dynamic range at a maximum, the feedback amplifier should provide sufficient current into the coil. The main limitation comes from the fact that modern systems are continuously using a lower and lower voltage supply, while coil size and weight of the moving body cannot be correspondingly reduced. Moreover, a heavier moving body of a sensor gives less thermal self-noise. A low-noise seismometer usually needs a larger current for the feedback coil.

The procedure of adjusting a sensor with feedback equalization consists of two stages. During the first step, a proper frequency

Electrochemical Seismometers of Linear and Angular Motion, Fig. 9 Device response vs. feedback depth (depths 1, 5, 40, 120)

response is made paying no attention to actual device sensitivity. In the second step, the required device sensitivity is adjusted.

The open-loop characteristics can be obtained by means of an external digital-to-analog converter (DAC) and analog-to-digital converter (ADC) with a harmonic response scan. The frequency response of the open loop outside the operational range is essential to ensure the system stability. After the initial open-loop response is obtained, the filter correction is made to adjust the feedback amplification, to make a flat response in the passband and predetermined behavior at low- and high-cutoff frequencies. The process is iterative in the same way as it was for the non-feedback devices.

The main difference compared to the non-feedback case is that the adjusting procedure gives a much more accurate response of a seismometer within the passband than for the non-feedback sensor. Generally the high- and low-cutoff frequencies are extended by 2–3 octaves. In parallel with the feedback adjustment, a fine-tuning of the output filter is done. In case the closed-loop response is actually flat over the passband, the device characteristics coincide with the output filter characteristics. This decreases the complexity of further device response presentation in terms of poles and zeroes.

The last step in manufacturing the device is the adjustment of its sensitivity. The operation can be carried out by adjusting the overall gain of the output filter's $H_{out}(\omega)$.

After this final adjustment, the resulting frequency response characteristic of a closed-loop device is measured and verified. The main point of this method is in simulating ground motion by adding of an external signal into the closed-loop circuit. This signal addition works in the same way as a real input signal. An external sine wave generator can be used to provide such a signal at various frequencies and thereby get a full calibration function.

The block diagram of the closed-loop calibration procedure is illustrated in Fig. 10 where the sine wave test signal from a generator is added to the closed-loop signal in the summation unit Σ . The signal disturbance introduced into the closed-loop and the output response are measured by an external 2 channel analog-to-digital converter.

The examples of the resulting calibration curves are shown in Figs. 11 and 12.

The closed-loop calibration procedure makes the subsequent maintenance and validation of a device possible with a common DAC–ADC and a reference sensor with verified sensitivity and noise performance. The test is carried out only by means of the

Electrochemical Seismometers of Linear and Angular Motion, Fig. 10 Closed-loop self-calibration

Electrochemical Seismometers of Linear and Angular Motion, Fig. 11 Seismometer response obtained by the self-calibration test. The actual CME-6011 sensor was used to generate an example

standard device connector and does not require any intervention into the sensor or disassembling the device. The presence of a shake table becomes unnecessary. The device sensitivity can be determined using either factory-determined calibration constants or by analyzing the simultaneous recording made with a sensor with known sensitivity. The noise performance of a device can only be obtained by analyzing the simultaneous record made by at least

two sensors placed close to each other. One of the approaches is to calculate non-correlating components in the signal of two sensors of the same type with identical parameters (sensitivity, phase response, passband). Another approach is to make simultaneous recording with a sensor with far better noise performance. In the latter case the noise can be calculated by subtracting the low-noise sensor's signal from the tested sensor's signal.

Electrochemical Seismometers of Linear and Angular Motion, Fig. 12 MET geophones and accelerometers

Overview of Commercial Electrochemical Seismometers

Broadband Seismometers

The MET seismometers available cover a wide area of applications from permanent seismic stations to seismic field surveys, borehole measurements, and autonomous ocean-bottom systems (OBS). All devices are characterized by robustness, reliability, light weight, and easy installation procedure. None of them require any type of mass lock in transportation or mass centering during installation. They are operable under tilts up to $\pm 10^\circ$ and more, and some models are able to operate under any tilt angles. This feature is extremely useful for OBS operation. The lightest and the most power-efficient models of three component seismometers like CME-4211OBS have weight of 2.2 kg and power consumption

of 90 mW during operation. The dynamic range for the best models is in the range 135–150 dB, while self-noise of the devices goes down below the lowest observed vertical seismic noise levels estimated by the New Low Noise Model (NLNM) in the 15 s–1 Hz range. The majority of models are equipped with closed-loop force feedback equalization. However, devices with filter equalization are lighter and use less power, which is essential for self-contained systems.

Seismometers for permanent installation have better noise performance due to heavier moving parts and are therefore more complex in design. These devices have the lowest cutoff frequency and due to that are less suitable for portable applications. However, for vault installation such parameters as power consumption and weight have less significance. Like other MET devices, they don't require any special arrangements during installation and operation. Models designed for self-contained systems, like field geological surveys with frequent location changes or for oceanic exploration, feature energy effectiveness, light weight, and compact size. Low-frequency cutoff as high as 0.1 Hz is more common for these instruments (Tables 1 and 2).

MET-Based High-Sensitive Geophones and Seismic Accelerometers

The main advantages of MET-based seismic geophones and accelerometers with negative feedback lie in their extremely high coefficient of conversion of mechanical motion into an electrical signal, the possibility of a significant (compared to a traditional geophone) expansion of the frequency range both in the low- and high-frequency directions, and the simplicity and reliability of the design (Agafonov et al. 2010; Agafonov et al. 2014). Until recently, the instruments of this kind were used almost exclusively for measurements in the low-frequency domain. However, the developments of recent years (Krishtop et al. 2012) have made it possible to produce the devices with an upper operating frequency that exceeds the values typical for most geophones.

The experience learned from the development of such sensors indicates that the optimal

operating characteristics are attained when MET-based sensors are equipped with an electrodynamic negative feedback mechanism. With a feedback, the instrument scale factor of 300 V/m/s is achieved without using any additional amplification, which is equal to or greater than that achieved by other known low-frequency geophones. At the same time, for a frequency range starting at 1 Hz, the MET geophones are much smaller than typical electrodynamic geophones.

The external view of sensors is shown in Fig. 12. MTSS-1001 is a single-axis, ultracompact, high-gain, 1-Hz seismic sensor. MTSS-2003 contains three orthogonal oriented MTSS-1001 seismic sensors. It is probably the

world's smallest tri-axis 1-Hz seismometer. MTSS-2003 is designed primarily for measuring small low-frequency signals. It combines high gain, small size, and low power consumption.

The 3-component high-performance accelerometer MTSS-1033A and its 1-component version MTSS-1031A are designed for strong motion seismic measurements, industrial vibration monitoring, vibration isolation analysis, etc. MET accelerometers combine very small size and high sensitivity over wide frequency band. The wide dynamic range, low distortion, high temperature stability, and competitive price make it ideal and cost-effective solution for various applications such as earthquake, strong

motion measurements, or structural monitoring. At the same time, unlike mechanical force-balanced accelerometers, the MET accelerometers cannot measure the DC component of the seismic signal. Although, the seismic signal is oscillating, the DC signal has a significant practical importance. The DC signal makes it possible to calibrate the sensor by rotating or tilting it relative to the gravity vector and to determine the sensor's axes orientation with respect to the vertical direction. In addition, the difference in

low-frequency phase behavior makes it difficult to compare the responses of a MET accelerometer and a mechanical DC accelerometer (Table 3).

Electrochemical Angular Motion Seismometers

Interest in the pure rotational seismometer is driven by the suggestion that adding a new type of measurements would allow to better characterize the response of the structures to seismic

Electrochemical Seismometers of Linear and Angular Motion, Table 3 The technical performance parameters for MET compact low-frequency geophones and accelerometers

Performance	MTSS-1001	MTSS-1041A	MTSS-1031A
Frequency range	1–300 Hz	0.1–120 Hz	0.1–120 Hz
Sensor noise	150 nm/s, rms over frequency range	110 ng/√Hz	150 ng/√Hz
Conversion factor	250 V/(m/s)	6 V/g	2.4 V/g
Maximum negative feedback depth	20	100	150
Maximum applied acceleration	–	±2 g	±4 g
Dynamic range	>110 dB	>110 dB	>120 dB
Non-linearity	<1 %	<1 %	<1 %
Orientation	Any direction	Any direction	Any direction
Weight	180 g	180 g	180 g
Temperature	“–55 ~ +65 °C”	“–55 ~ +65 °C”	“–55 ~ +65 °C”
Power	<80 mW	<80 mW	<80 mW

sensing technology, is presented in Fig. 4 above. The sensor consists of the toroidal channel, filled with an electrolyte, and the sensitive cell placed across the channel, converting liquid motion into the electrical response. An expansion volume is used to compensate for the temperature expansions of the liquid. Electrochemical sensors are probably the only rotational sensors which are commercially available at a reasonable cost with a resolution appropriate to seismic applications. Figure 13 shows the spectral noise density spectrum of rotational electrochemical sensors compared with other commercial devices measuring rotation. The parameters of some of the commercially available electrochemical rotational seismometers are shown in Table 4. The independent test data can also be found in Bernauer et al. (2012b).

Summary

The electrochemical seismometers offer an alternative to regular electromechanical devices. They are compact, robust, and easy to install and provide good quality data. The operation principles of the electrochemical seismometers are based on using the charge transfer variations due to electrolyte motion in the four-electrode

electrochemical cell. Among the commercial devices developed on the base of this technology are broadband seismometers, compact high-sensitive MET geophones, accelerometers, and unique angular seismometers.

Introduction

Responses to significant earthquakes are challenging and complex. This entry explores the key aspects of earthquake response that are particularly pertinent to the context of earthquake engineering.

Managing the risks of hazards, such as earthquakes, is not merely responding to them when they occur or even preparing effectively for those responses. Contemporary emergency management applies a much broader brush than the 1950s era, response-focused “civil defense” approach that held sway in most jurisdictions until the 1990s or early 2000s. Contemporary comprehensive emergency management has increasingly encompassed: developing adequate appreciations of the risks that communities face; working to enhance resilience, reduce or mitigate exposure to those risks, and build readiness or

Jon Mitchell was NZ Coordinated Incident Management National Steering Committee from 2007 to 2014 and Massey University, Joint Centre for Disaster Research, 2014 to present

David Brunson was Chair, NZ Lifelines Committee 1999 to present and NZ USAR Engineering Leader from 2004 to 2012

preparedness to respond and recover; respond in a coordinated, adaptive, and effective manner including all relevant organizations and effected communities; and initiate regenerative recovery parallel with response so as to further enhance resilience and make the most of the opportunities that disaster provides to communities.

The 1980s and 1990s saw the development of the “all hazards” approach to emergency management, intended to broaden the application of preparedness for hazards beyond a handful of locally relevant natural hazards and the then diminishing threat of nuclear conflagration, with the fall of the Berlin Wall and the end of the cold war. The all hazards approach tended to suggest that the arrangements, capabilities, and resources put in place by government agencies at all levels for the major hazards they faced could then be applied any and all hazards that might then arise.

The world has experienced increasing exposure to natural hazards and their consequences since the 1960s, as populations have boomed in climatic and geological risk-prone areas in less developed countries and as communities and industries in developed economies became increasingly dependent on technology, particularly electricity and telecommunications. Increasing exposure to risks has resulted in continual improvement and refinement of approaches to managing risks internationally, culminating in the United Nations making the 1990s the “International Decade for Natural Disaster Reduction” and the initiation of programs such as the United Nations Office for International Disaster Risk Reduction (UNISDR).

UNISDR projects, including the “Hyogo Framework for Action 2005–2015 Building the Resilience of Nations and Communities to Disasters,” have seen emergency management, and disaster risk management in general take a more comprehensive turn. Nations and communities, in their own ways, are increasingly attempting to understand the natural and human-induced hazards that they face; to inform risk reduction legislation, regulations, and programs; to build community and organizations’ resilience and

response capabilities; and, of more relevance to this entry, to develop and deliver effective response and recovery capabilities and outcomes.

This entry commences with an overview of more formal leadership and coordination of responses. It then goes on to cover the topics of monitoring and analysis of ongoing seismic activity during response; acquiring, analyzing, managing, and sharing information during disaster response; capturing and making use of physical and social impact data; urban search and rescue (USAR); medical response; emergency welfare; and emergency food, water, and sanitation services. This entry concludes with discussion of post-quake building management and critical infrastructure or lifeline utility coordination: essential elements of response and recovery.

Leadership and Coordination

When significant earthquakes strike, the challenges for those in positions of leadership or who are responsible for response coordination are many and varied. Not the least due to the reality that affected communities, ethnic and social networks, businesses, service clubs, and faith organizations, emergency services in the area at the time will be mounting their own responses, while official responses will generally still be regrouping and reestablishing communication with their field resources and external support. The very nature of damaging quakes makes them some of the most difficult hazards to manage responses to, as earthquakes tend to undermine the ability of response organizations to deliver their services more than other hazards tend to.

Leadership and coordination, nonetheless, are crucial to ensuring that the needs of affected communities and the services they depend upon are met in as timely, effective and equitable manner as possible. Key to effective emergency leadership and coordination is legislation that adequately provides for the situations that are likely to arise from major hazards.

The legislative requirement to identify the major hazards and risks that respective national,

Emergency Response Coordination Within Earthquake Disasters,

Fig. 1 Basic response coordination structure – NZ CIMS manual (Ministry of CDEM 2014)

state, regional, and local communities face is an essential foundation to emergency management – as are legal responsibilities to plan at national and subnational levels to manage hazards and their risks holistically.

Coordination of responses to the immediate and longer-term consequences of earthquakes is considerably more important than command and control-style leadership, as no single individual or organization can have adequate knowledge of impacts and response to be able to comprehensively lead or direct responses. More implicit coordination within and between organizations and communities is more influential than individual or organizational leadership and direction. The concept of disaster response management that is increasingly seen as most effective in understanding and delivering responses that actually work is “network-centric operations” (Von Lubitz et al. 2008) or, in short, net-centric operations.

The impacts of earthquakes tend to not only cause buildings and other vertical and horizontal infrastructure to fail or be compromised but also to cause injuries, distress, entrapments, and fatalities. They also disrupt response capabilities, despite how well planned and resourced those capabilities are, due to overload and damage to telecommunications systems, the initial confusion in the community and official responders, and direct impacts on responders and their equipment and facilities – as well as their families, their homes, and the services they depend upon.

Effective coordination depends on a range of factors. An essential prerequisite is a shared understanding of and commitment to response coordination structure, roles, terminology, and processes. Each nation tends to have adopted or developed an incident coordination, command, or management system adapted to suit the national

context and, if necessary, that of its neighboring or closely related nations. All incident management systems provide a common structure, roles, processes, etc. for overall response coordination at various levels of response. Each response organization applies the standard system to their own operating procedures to greater or lesser degrees, depending on the requirements of the overall system and any statutory or regulatory mandate attached to it.

Incident management systems tend to provide an organizational structure and hierarchy with a response director or controller in the senior position, albeit often under the direct influence of senior appointed or elected officials. Reporting to the “controller,” “director,” “commander,” or similar, are managers of response management functions, including public information management, operations, intelligence, planning, and logistics (Fig. 1).

Note: “PIM” is public information management in the New Zealand context and “public affairs” or similar in other contexts.

Response Coordination Principles

Levels of response coordination tend to include:

- **Site** – management closest to the response field activities themselves. In an earthquake context, this will tend to be a large building, block or buildings, or a small geographic area encompassing areas of structural damage and geological damage, including liquefaction and rockfall, landslide, etc. or social impact or social support.
- **Local** – coordination and direction of response activities and resources in support of site-level response, often at suburb or

municipal level. Management of local critical infrastructure will usually be represented in incident management organizations at this level of coordination.

- **Regional** – support, coordination, and direction of local response activities and resources, often at the political level above municipalities, such as county, region, or prefecture.
- **State and or national** – support and coordination of resources and activities in support of lower levels of response. Statewide or national critical infrastructure providers, in some cases clusters like utilities and service providers, link into the requisite level of official response coordination.

Incident Coordination

Incident or site-level coordination tends to occur close to the area of impact and focus of response, from what is usually referred to as an “incident command post,” “incident control point,” or similar. Incident management at this level is usually populated by low-level managers of the agencies contributing to the response and may include supervisors of field components of critical infrastructure providers. Despite this use of the term “incident,” the same term is often applied to all levels of emergency and disaster.

An incident control point can be provided by one person or an incident management team of very few to tens of individuals from the range of agencies responding directly to the incident and those supporting the response organizations. Higher-level coordination facilities, which tend to be preestablished and equipped, are ideally post-earthquake operational in areas where that hazard is prevalent and may be staffed by a few individuals and agencies or by hundreds of personnel from a wide range of government agencies, nongovernment organizations, and the private sector.

Key tools of incident management systems include:

- Collective development of “action plans” to provide a basis for explicit response

coordination and collaborative delivery of tasks assigned within actions plans at each level of response

- “Planning cycles” providing a systematic process for the development, delivery, and review of action plans and resultant actions
- “Situation reports” compiling relevant contextual, impact, and response information within the respective level of response coordination to inform decision-making
- “Status reports” and “incident reports” that inform situation reports and the maintenance of ongoing shared situational awareness
- “Resource requests” from one level of response coordination to that above it for resources that are not able to be acquired at sites or within the respective level of coordination
- Situation briefings, information sharing, informal communication, cooperation, and shared situational awareness support “implicit coordination”
- Intelligence collection, analysis and dissemination cycles, and action plan and task plan development are components of “explicit coordination”

Legislation

All nations have response management legislation of some sort. Emergency management legislation tends to provide the requirement or mandate to plan for emergencies and appoint appropriately trained and experienced individuals to response direction or control roles for which a range of emergency powers are provided for in the legislation. These powers may be retained at the national or state level, but are usually reflected in similar powers within subsidiary levels of government. Emergency or disaster management legislation usually provides for a senior elected official to declare a “state of emergency,” “disaster declaration,” or similar for the respective level and/or lower levels of government – releasing emergency powers and requiring response organizations, critical infrastructure providers, and the media to act in a coordinated manner.

Phases of Emergency Response

Initial objectives of emergency response are around providing support to injured, trapped, isolated, and evacuated individuals and groups. Much of the initial active field response will be focused on search and rescue in areas where buildings and facilities have suffered damage during the initial or subsequent shaking, structural failure, liquefaction, inundation, fire, or other consequential hazard. Search and rescue may continue for weeks in some cases following the initial quake, if there is likelihood of survivors being located and extricated.

While search and rescue activities are underway, those who are either sheltering in place or have evacuated, either under their own auspices, assisted by other members of the community, or by way of a managed or compulsory evacuation, will require further support. This is discussed further under “Emergency Welfare and Emergency Food and Water Supplies” later in this entry.

Planning for and establishment of much longer-term social/community, infrastructure, economic, and environmental recovery management programs is required to be activated parallel with initial and ongoing response activities. Recovery efforts that wait for the official response phase to be formally completed will not be able to maintain or make the most of the focus and momentum established during response (Ministry of CDEM 2004). Recovery management, as with effective response management, can only be efficiently achieved when sufficient planning, legal mandate, resourcing, and professional development have been put in place and maintained prior to any significant emergency occurring.

Public Information Management

A key component of managed responses is public information management, the process of engaging and communicating with those affected by or who have an interest in the disaster and its aftermath, through the media, directly, and, increasingly, through social media.

Whether response organizations engage with, manage, monitor, or support the media and, increasingly, social media, both traditional and social media will have a significant interest in the emergency itself, consequences, pre-organized and emergent community-based, and official responses. This will be all the more so when there has been appreciable damage, injuries, or deaths.

Ensuring that the affected community, those supporting those affected, the wider area, the nation, and, in significant enough emergencies, other parts of the world are aware of what has occurred, what those affected should do, what others should do, and what official organizations are doing fall under the heading of “public information management,” “public affairs,” or a similar title within emergency responses.

Public information management in major emergencies, just like overall responses themselves, is most effectively managed in a multiagency context, in a Joint Information Centre, under the coordination of the leading government agency. This allows for a consistent and well-directed messaging to be delivered by a composite team of communications officials and the wider range of organizations involved in the response.

Traditional print media, particularly newspapers and electronic media, including social media, are relatively vulnerable to the impacts of earthquake, either directly when local production and distribution or transmission infrastructure are compromised or when electricity or access to or within the affected communities is interrupted. Purpose-designed flyers produced by the response organizations and delivered directly to affected homes, communities, evacuation centers, and receiving communities may be essential during response, particularly where media that communities usually depend on may be disrupted by the event and its consequences.

Ensuring that appropriate people are adequately trained and available to act as spokespeople for various organizations involved in response is essential. Some spokespersons will be the response leaders within the organizations involved themselves, such as CEOs [or city managers] of affected and responding local

authorities and infrastructure providers, as well as response controllers and senior emergency service managers actually managing the response. Politicians have an important role to play in response, with mayors usually taking spokesperson role at a local level and responsible cabinet members doing so at state or national level, and prime ministers, governors, or presidents doing so in more challenging emergencies that warrant higher-level political engagement.

One of the risks of attempting to assimilate community, agency, media, and social media information on behalf of the entire response and to produce the outputs to affected communities in a timely manner in particular is that the processes of doing will be slowed by the need to develop outputs in a collaborative manner. Bureaucratic development of outputs combined with compromised means of communication can result in critical information not reaching key audiences in a timely enough manner – something that needs to be kept in mind and mitigated prior to and during responses.

Engaging with affected communities is a crucial aspect of public information management, particularly where community responses are not well integrated into the official response and recovery activities. Including spontaneous and organized community response and preexisting and post-event community groups as partners to public information management is increasingly seen as critical to effective response and recovery efforts.

Significant events will not only receive widespread coverage outside the affected area but may result in hundreds and possibly thousands of reporters and production crews converging on the affected area and coordination centers and sites of particular interest. Dealing constructively with this number of additional personnel and the activities, some potentially risky or at least intrusive or distracting, has to be taken into account in planning for and delivery of response and recovery public information management.

Event Hazard (Seismicity) Monitoring

While the aftershock sequence cannot be prescribed or predicted following a major

earthquake, it is important that there be as good an understanding of the characteristics of the likely aftershock sequence as possible. The communication of this information in a timely way requires the specific integration of national seismological representatives within operational structures. Information about the possible magnitude, intensity, and location of aftershocks is of particular interest to USAR teams, those involved with rapid building assessments, and for public information purposes.

Through their training, the engineers involved both with USAR (Urban Search and Rescue) teams and the rapid building assessment operations have an expectation of major aftershocks of typically up to a magnitude less than the main shock to occur in the days, weeks, or months following, but possibly up to the same magnitude as the main shock.

For USAR teams, as the likelihood of rescuing live people from collapsed structures diminishes with time following the main shock, the “risk vs. reward” equation changes, and therefore a sense of the likelihood of significant aftershocks is a useful input.

Engineers and others undertaking rapid building assessments have a longer time frame to consider as they assess the suitability of damaged buildings for continued occupancy. The placards they post on buildings should take into account the additional damage that could occur from aftershocks in the days, weeks, and months following the earthquake and prior to detailed damage evaluations and repairs being undertaken.

Assessment of the short-, medium-, and long-term seismicity effects after a major earthquake is important as the response transitions to recovery. This may, for example, lead to an increase in the seismic design coefficients used for repairs and rebuilds due to the heightened seismicity, as happened following the Christchurch earthquake in February 2011.

The nature of the expected aftershocks can broadly be characterized from the fault activity which caused the earthquake itself. For example, earthquakes that occur on established and active faults close to plate boundaries typically generate few significant aftershocks, and these will

generally have the same directionality. In contrast, earthquakes that occur away from plate boundaries (intraplate earthquakes) on “new” faults that have not previously shown evidence of surface expression can generate aftershocks which migrate, with much less predictability about the number of significant aftershocks and their intensity and directionality.

The post-event seismicity is typically expressed in probabilistic terms, which can take the form of “the probability of an aftershock of magnitude range (e.g., M6.0–6.4) occurring in a given region within a specified period of time.” This form of estimation often uses different seismicity models, depending whether the time frame is short term (e.g., months or a year) or longer term (e.g., 20 or 50 years).

Assessment of secondary risks should also be undertaken and must be considered within the post-quake context. These include those that are consequential in addition to the primary seismic hazard, such as tsunami and landslide/rock-fall, liquefaction, natural and technology-related environmental contamination, as well as consequentially unstable slopes and land susceptible to subsidence and increased flood risk.

Emergency Information Management

Managing impact and response information is a particular challenge during damaging earthquakes, particularly if inadequate thought and preparation has gone into this function prior to the event or key components of information collection, analysis, sharing, management, storage, or dissemination are compromised by the event itself. The benefits of a well-developed incident management system and supporting information management systems are vital to effective quake response activities.

Contemporary information management relies on networks and equipment which when, unless designed, constructed, supported, and used appropriately can be particularly vulnerable to direct or indirect earthquake interruption.

Telecommunication providers are an essential element in the resilience-building work of such

critical infrastructure groups prior to and their efforts to restore services during emergencies and after emergencies.

Organizations with roles in response, including critical infrastructure providers, are better able to manage and share information during emergencies when they have invested in post-quake accessible and resilient data backup services, ruggedized or robust and seismically secured information management hardware, and alternate means of communications, such as voice and data over satellite or radio. Even resilient data storage, management and communication organizations with response roles also have to have paper-based systems to fall back to, at least temporarily, in the event of their first line of alternate arrangements being compromised or overwhelmed.

Effective response management depends on emergency-related information management applications and operational procedures that are compatible with partner organizations, fit for purpose, well trained, and exercised.

Cloud-based data storage and email systems are becoming increasingly popular in not only emergency response-focused information management but in business continuity and disaster recovery processes. Software and equipment that are intended for emergency purposes and personnel required to use or manage them are considerably better able to meet response and recovery needs if the response roles are integrated as much as possible into business-as-usual practices.

Impact Overview: Rapid Impact Assessment

One of the first tasks of affected communities and organizations, and the emergency response organizations supporting them, after a hazard such as an earthquake causes damage is to carry out a rapid impact assessment. These usually occur within 8–48 h on the incident occurring to:

- Assist in determining what ongoing or new risks may be present
- Planning initial response actions

- Acquiring, activating, and tasking necessary initial resources
- Provide the basis for more detailed needs and structural assessments

Rapid impact assessment is much less about building-by-building, household-by-household, and facility-by-facility assessment generally initiated several days into the response, but about quickly gaining a sufficiently detailed and reliable intelligence picture of the known and likely direct and indirect impacts of the hazard. The process of planning, tasking, collecting, analyzing, and disseminating rapid impact assessment data should follow the intelligence cycle process used in all aspects of emergency response to inform initial and later action planning processes.

Analysis of earthquake risk, including estimates of likely impact and, particularly in relation to critical infrastructure and vulnerabilities of particular and interrelated infrastructure, can greatly assist rapid impact assessment. Knowledge of quake likelihoods and consequences can change relatively rapidly as aspects of earthquake science and knowledge improve.

It is essential for those preplanning or actually managing rapid impact assessment to use quake risk studies to inform their work where any such studies are available. An example of such a study carried out recently is that for the Wellington region, New Zealand (Cousins 2013), which provides estimates of between \$NZ1 billion and \$NZ16.5 billion in damage in varying scenarios generated by the seven major fault lines known in the city and in the nation's capital, with a population of approximately 460,000 and 195,000 buildings where they are built on or adjacent to. The damage would include up to almost 7,000 building failures caused by shaking, geological failure, or tsunami, up to approximately 2,000 fatalities and 9,300 serious injuries from earthquake, and 3,500 fatalities and 7,000 injuries from tsunami. Pre-event impact estimations such as these are of considerable assistance in determining impact assessment, response, and recovery resources that are likely to be necessary when real disasters strike.

In the first few hours and days after a significant earthquake, telecommunications are likely to be compromised, and personnel available to carry out physical and social impact assessments will be in short supply. Therefore, for impact assessment to be conducted efficiently and effectively, it may be necessary for the coordinating emergency management agencies and emergency services to plan and prioritize the deployment of resources in pre- or response-determined sectors.

Impact data collection has traditionally been carried out in a paper-based environment, but electronic data collection, often with digital photographic records and GPS location data, is becoming increasingly affordably feasible – even in the immediate wake of earthquakes and similar hazards. Handheld devices, including smartphones, tablets, iPads, etc., and purpose-designed or business-as-usual applications are revolutionizing the collection, management, and application of data in virtually all emergency, incident, and disaster management contexts.

Although standard telecommunications services will often be compromised or at least overloaded in the first few days after an earthquake, data can be readily transferred to recipient databases by way of direct data download at the impact assessment base of operations or respective emergency operations center.

Rapid Physical Impact Assessment

In the emergency response coordination context, post-earthquake, rapid impact assessment tends to focus first on identifying sites and areas when search and rescue may need to occur – usually multistory buildings that have failed or been seriously compromised and buildings, roads, bridges, ports, airports, and other geological features that may be required for evacuation and emergency response access and egress.

Identification of actual and potential environmental contamination, from analysis of preexisting records of contamination risks, contamination identified or reported in the immediate response or in subsequent managed reconnaissance tasks.

Early assessment also includes determining whether buildings, other infrastructure, or geological features potentially damaged in early shocks may fail later, either of their own accord or due to later seismic activity.

Rapid impact assessment informs immediate planning and management of tactical functions such as search and rescue, evacuation orders and support, public information messaging, etc., as well as more planning for more strategic activities and resourcing.

Rapid physical and social impact assessment tasking, data collection, analysis, and dissemination are usually managed by the emergency management arm of the local or regional/county government involved, in conjunction with local emergency services, particularly fire and police resources working in or supporting immediate response in the affected areas.

Rapid Social Impact Assessment

The process of rapid social impact assessment is activated alongside rapid physical impact assessment – informally by communities and more formally by government and nongovernment relief, social service, and emergency management organizations. Social impact assessment and emergency social/welfare services are usually coordinated by the emergency management arm of the respective local or regional government, supported by state, national, and international entities.

Even in post-quake international disaster relief situations, the responsibility for authorizing the cross-border entry of search and rescue, impact assessment, and relief personnel and their deployment and activities within the affected areas lies within the government of the recipient country and, where delegated authority exists, within the government of the local jurisdiction involved.

Social impact assessment includes gathering data on known needs and making estimates of likely needs based on known data and knowledge of needs generated in similar events in comparable communities elsewhere.

Emergency social needs include the basic hierarchy of needs: safe air, water, and food, a

safe place to sleep, and adequate sanitation. Immediate needs then extend to social reconnection, particularly for family members separated as a consequence of the emergency and identification and support of the vulnerable, whether due to pre-emergency circumstances or as a result of the emergency.

Most social impact data is collected by personnel assigned that responsibility in teams tasked to carry out survey of individuals, families, or groups sheltering in place, seeking support at relief centers, or evacuees in transit or at reception centers or group lodging. However, rapid social need assessments can also be augmented by data collected by those carrying out rapid physical impact assessment, particularly if those gathering data on physical impacts have been prepared to observe and gather social impact information.

Residential impact assessment can often be most effectively carried out in conjunction with physical impact assessment, through the establishment of composite teams of building assessors and social services workers. In areas where there are larger buildings, impact assessors and engineers are likely to be deployed on behalf of building owners and insurance companies relatively early in the response. Opportunities to coordinate and share at least outline impact data between public and private assessors should be pursued. Private assessors should at least work under the safety and access requirements imposed by emergency management agencies.

Access to damaged areas is likely to be controlled by emergency services or emergency management agencies early in the response. If that is the case, impact assessors will need to be required to carry pre-authorized means of identification or identification and access documentation or printed cards developed for the particular response. Assessors will also be required to use personal protective equipment and regular reporting procedures as prescribed by the coordination entity or at standard occupational health and safety practice for the respective jurisdiction.

Impact and needs information is of little use if it is not made available to those delivering

immediate support services or planning for larger-scale longer-term search and rescue, safety, relief, and eventual recovery programs. It is essential that all impact assessment data captured during response are captured and collated at a local level and then made available to response and relief organizations in a timely manner. Some users of impact assessment data, such as rescue teams and risk managers, will need detailed reports and data feeds, while others, such as social service providers and governance bodies, will require more aggregated, area-wide data.

Impact assessment is most effective when it has been planned and resourced in sufficient detail prior to an emergency and has ideally been tested through exercising both data collection and analysis in particular.

Urban Search and Rescue

Urban search and rescue (USAR) involves the location, rescue, and initial medical stabilization of victims trapped in confined spaces following a structural collapse. USAR is an integrated multiagency response beyond the capability of normal rescue arrangements in most jurisdictions. In addition to rescue technicians, USAR teams include medical and canine search and rescue engineering capabilities.

The canine search component of a USAR team focuses on carrying out rapid searches over and within collapsed or seriously damaged structures. Being trained to operate remotely from their handlers, the search dogs are able to go into areas that may be considered too dangerous for rescue technicians. By alerting when they encounter trapped live people, they provide a focal point for search operations and the other equipment that they have, thereby assisting with prioritization and saving significant time in a search and rescue operation that covers a large area or numbers of buildings.

The engineering component of a USAR team assists with the identification, monitoring, and reduction of hazards (within site) and provides detailed/specific structural engineering advice where required. This includes advice on the least dangerous points of access to areas of

structural collapse where the most complex rescues may be required, having due regard to both the current stability of the structure and potential impacts from following aftershocks. Ideally USAR engineering teams should contain a geotechnical engineer, as the threats of further movement posed by unstable hillsides (landslip and rockfall) add considerable complexity to earthquake-affected areas.

The principal source of reference in relation to USAR practice and arrangements is the UN-based International Search and Rescue Advisory Group (INSARAG) www.insarag.org. The focus of INSARAG is the development of standardized guidelines and procedures and sharing of best practices among national and international USAR teams and defining standards for minimum requirements of international USAR teams. The INSARAG Guidelines provide frameworks for the response operation for the country affected by a sudden-onset disaster causing large-scale structural collapse, as well as for international USAR teams responding to the affected country. They also outline the role of the UN assisting affected countries in on-site coordination.

Irrespective of the scale of the USAR response to a significant earthquake event, the Local Emergency Management Authority (LEMA) is the ultimate responsible authority for the overall command, coordination, and management of the response operation. The LEMA can refer to local, regional, or national authorities or combinations thereof, which are collectively responsible for the disaster response operation.

In the rescue response following a major earthquake, the operations focal point is the On-Site Operations Coordination Centre (OSOCC). The OSOCC is established close to the LEMA and as close to the disaster site as is safely possible. It provides a platform for the coordination of international responders and LEMA. The OSOCC is established by the UNDAC team or by the first arriving international USAR team, who will then hand over the OSOCC to the UNDAC team when they arrive. An outline representation of the relationships between these aspects of response is provided as Fig. 2.

Emergency Response Coordination Within Earthquake Disasters, Fig. 2 On-Site Operations Coordination Centre (OSOCC) Relationships (Source: C3Fire.org)

The main purpose of the OSOCC is to assist the LEMA with the coordination of international and national USAR teams as well as establishing intercluster coordination mechanisms (e.g., health, water/sanitation, and shelter).

The United Nations Disaster Assessment and Coordination (UNDAC) Team is dispatched by the UN to sudden-onset emergencies when requested to do so by the affected Government or the UN Resident Coordinator in the affected country. UNDAC Team members are trained emergency managers from countries, international organizations, and UN OCHA. The UNDAC Team assists the LEMA with the coordination of international response including USAR, assessments of priority needs, and information management by establishing an OSOCC.

The activities and processes within each of the USAR phases of *Preparedness*, *Mobilisation*, *Operations*, *Demobilisation* and *Post-mission* are elaborated upon within the INSARAG Guidelines.

In addition to national and international USAR teams, many jurisdictions have local or regional response teams that are trained in a range of operational capabilities, including surface search and rescue. Their role is typically to assist the emergency services and the LEMA and to provide liaison with and support for USAR

teams. The input from response teams following a major earthquake varies with time following the event and ranges from assisting with initial surface rescues in the immediate aftermath prior to the arrival of national USAR teams to detailed searches of less damaged buildings to ensure no trapped persons are present through to providing safety advice and support for engineers undertaking rapid building assessments.

Medical Response

Most injuries as a result of earthquake are caused by falling furniture or internal or external fittings and architectural features. These can range from minor cuts and sprains to more serious lacerations, fractures, crush injuries, and, in some instances, burns. A smaller proportion of injuries are caused by individual falls caused directly by shaking. The most serious injuries and fatalities tend to be caused by failure of parts of structures that casualties were either in or adjacent to at the time that the quake or significant aftershocks occurred.

Mass injuries and fatalities, and infrastructure and environmental damage for that matter, tend to also occur in the more rare instances when tsunami accompany or follow a serious earthquake, as the tsunami surge reaches shore either near to or distant from the epicenter of the quake. As demonstrated in the recent earthquakes and tsunami in Japan and in 2004 in the Indian Ocean, earthquakes and tsunami can present substantial initial and consequential fatalities, injuries, infrastructure, and ongoing environmental contamination that may continue to have effects for a very long time.

Earthquakes bring multiple challenges to those tasked with providing medical support to those injured in the quake and its aftermath. The most challenging situations are those where casualties are entrapped within damaged building or within debris from damaged buildings or failed built or geological structures. Access to and treatment, or extraction and then treatment, of casualties may be achieved in the early stages of response by others on the scene at the time or

spontaneous formal and informal responders converging to sites of structural collapse.

Significant medical support to entrapped, ambulatory, and evacuated casualties will be required following earthquake and may extend as far as limb amputation to enable timely extraction and specialist support to sufferers of crush syndrome or occasionally prolonged dehydration following protracted entrapment.

Earthquakes will often have serious implications for health services and supporting infrastructure in the vicinity, as utilities services and access for ambulances are compromised; community-based health services, general practices, and hospitals, particularly multi-floor facilities are damaged; the homes, places of learning or care, and work places of health workers and their families are also damaged or isolated; and health workers or family or friends become casualties themselves. Even in earthquake-resilient health facilities, damage will be experienced, not the least to supporting infrastructure and often older neighboring facilities that are less resilient.

Following significant earthquakes and similarly damaging emergencies, the scale of injured who self-report or are transported to existing and possibly damaged on-site or makeshift triage and treatment centers setup on-site will be beyond normal mass-casualty planning and experience. Innovative approaches will be required to meet needs generated. Preplanning, training, and exercising for earthquake-scale medical responses will substantially enhance site response, field triage, medical center and hospital resilience and response, and local, regional, and higher-level health service emergency coordination.

Engineering support is critical to health-care providers, initially in terms of damage assessment and operational advice, in the immediate aftermath of earthquakes, as decisions are made on the least risk-prone facilities in which to conduct emergency medical care and whether evacuations are required from possibly damaged facilities.

Hospital emergency responses, ideally planned for and resourced well prior to them

being required, will include not only triaging and treating the injured but also dealing with damage to their own facilities and impacts of staff capabilities, coordination of service delivery and patient care with partner health and social service providers, decanting of less-urgent patients from the service, and transfer of higher acuity patients to unaffected or less affected facilities elsewhere.

Retirement homes and associated hospital and support services are a growing part of health services in many communities, due to aging populations and decreasing family size. The concentration of vulnerable people in elderly care facilities or receiving support in the community becomes a priority for local health services, both in the area affected and, potentially, recipient communities in the event of a significant self- or managed evacuations occurring.

Emergency Welfare

Direct and indirect impacts on humans are the main focus of response and recovery activities following earthquake. Emergency welfare or social services are the formal and informal processes put in place to assist those affected to meet their basic needs following emergencies. These needs are created when people no longer have access to the essentials of life, including accommodation or shelter; personal safety and security; food, water, medication, sanitation, and hygiene; care for dependents and vulnerable people; clothing; means of income; and psychosocial support.

The majority of emergency welfare services tend to be provided informally by the impacted communities themselves, along with their preexisting social networks; extended families; neighborhoods; faith, ethnic, and community service groups; business associations; and spontaneous volunteer groups formed in the wake of the emergency. These efforts are augmented and, where possible, supported by more formal service delivery arrangements.

Initial emergency welfare response tends to focus on making emergency shelter, food,

water, and relatively hygienic toileting services available to affected resident, transient, or visitor communities. These services are provided in community emergency centers, evacuations centers, or other facilities established to centralize services and physical resources in relatively safe and secure locations or dispersed within the affected communities if residents are sheltering in place but with access to normal services compromised by the effects of the earthquake.

Public facilities, such as community centers, sports facilities, halls, or schools, will often be used in formal and informal welfare support – assuming these facilities remain relatively intact. People who have evacuated from their homes, workplaces, or visitor accommodation will tend to congregate open spaces such as parks and playing fields, particularly where built facilities are unavailable or insufficient to meet local needs or community members are reluctant to enter buildings following earthquake. Temporary tent communities will often be established by people who are reluctant or unable to remain in their homes but who want to remain in their communities.

Emergency Food and Water Supplies

The images of food products broken and strewn across supermarket floors, collapsed shelving in warehouses, damaged roads and bridges, burst water pipes, and lines of vehicles at petrol stations are common scenes in news coverage after earthquakes. The realities of this for the affected communities run much deeper.

Earthquakes cause damage and contamination to water reticulation systems and to food supplies in people's homes, retail and wholesale food facilities, as well as food processing plants. Transport routes, including road, rail, water-based, and airport infrastructure into the affected areas, will be damaged to varying degrees, reducing supplies for at least days and often weeks or months.

Regional, state, or national food supply wholesalers are better able to reestablish supply chains more readily than emergency management

agencies sometimes give them credit, with alternative food supply logistics arrangements seldom being required to be established as part of official responses. It is essential, however, that food suppliers are included in emergency preplanning, relationship-building, and exercises to ensure that their needs and capabilities are realistically taken into account of and included in responses.

Distribution of food within affected communities tends to be more difficult to reestablish as retail premises and transport routes within the quake zone may well be out of commission for at least several days. Community engagement, preparedness, or resilience-building programs that encourage community members, groups, and businesses to have food and water supplies for several days will enable them to support themselves more readily, while formal and spontaneous arrangements are put in place.

Post-earthquake Building Management

In broad terms, a post-earthquake building management program is comprised of three phases:

- Overall damage survey
- Rapid building assessments
- Detailed damage evaluations

The *overall damage survey* is typically carried out as part of the immediate response by emergency services personnel and local authority staff, as referred to under *Rapid Physical Impact Assessment* above.

Rapid building assessments are generally undertaken by a number of small teams comprising volunteering engineers and other building professionals working with local authority building officials.

The objectives of a rapid building assessment process are to:

- Confirm where damage to buildings is concentrated to assist response and recovery decision-making
- Indicate whether physical action is to be taken to enable, restrict, or prevent access to individual buildings

- Commence the process of systematically gathering data on damaged buildings that will facilitate the planning and monitoring of longer-term recovery actions and reoccupation

The outputs from a rapid building assessment process are posted placards on the buildings and completed forms summarizing the damage observed and placards posted that are returned for entry into the database of the respective local authority or other responsible agency.

The focus of the rapid building safety evaluation process is on *immediate public safety*, not the provision of an engineering assessment service to building owners. It is an initial triaging process, akin to initial medical assessments at the scene of a large emergency or in a hospital emergency department. Buildings that have sustained visible and significant structural damage are marked via a placarding operation as not being suitable for reoccupancy. Other buildings that do not show signs of visible damage or movement may be suitable for occupancy, but they require further attention subsequently from building owners and their engineers when resources become available.

Rapid building assessments are just that – undertaken quickly in the face of potentially large numbers of buildings to be appraised within an affected area. Rapid assessments of only the exterior are expected to take of the order of 10–20 min, while rapid assessments involving exterior and interior inspections can take anywhere from 1 to 4 h, depending on the size of the building. These assessments are almost always undertaken without recourse to structural drawings.

The coordination of a rapid building assessment operation requires an operational structure that links between the local jurisdictions' building control unit and the emergency management leadership arrangements. As any such operation requires considerable follow-up activity by the affected council(s), it is important that the operation is integrated as much as possible with building control officials, particularly the leadership of the operation and management of data. Hence, a

considerable amount of planning and preparation is required prior to an event.

The following key roles are suggested for inclusion within the rapid building assessment operational arrangements and leadership structure:

- Building assessment manager
- Technical and process adviser
- Central business district/commercial technical lead
- Residential technical lead
- Engineering resource coordinators
- Information management coordinator
- Regulatory process support (transition management)

The scale of the event (and hence rapid building assessment operation) will dictate whether all of these roles are required to be filled.

Detailed damage evaluations are generally carried out by structural and geotechnical engineers specifically engaged by building owners. They involve accessing all available information, detailed interior inspections, and performing specific calculations where required. They can take anywhere from one day to a week or more, depending on the size of the building and the type of damage. Detailed damage evaluations for critical facilities, particularly hospitals, should however be undertaken in the immediate aftermath of an earthquake, and this requires appropriate priority response agreements to be established with engineers familiar with the facilities prior to an earthquake.

Lifeline Utility Coordination

The utility services sector is invariably complex in a day-to-day context, much less in a post-earthquake situation. Within the key sectors including water, energy, telecommunications, and transport, there are typically a range of providers.

The coordination of the information and actions across the utility sector following a major earthquake is accordingly complex and requires specific planning. The specific

coordination arrangements will vary depending on the legislative structures and operating arrangements in place. The key common feature is for such arrangements to enable a strong linkage between the utility sector (collectively) and the emergency management sector. This linkage needs to be active in nonemergency times, given the emphasis that should be given to risk reduction and preparedness.

The objectives of post-earthquake utility coordination are to:

- Coordinate the actions of lifeline utilities and emergency/disaster management organizations to provide a safe and effective response
- Support the restoration of lifeline services as quickly as possible

Utility coordination functions include:

- Managing information flows
- Monitoring impacts
- Communicating lifeline utility status information within the respective coordination center (s)
- Facilitating any support required by utilities for emergency/disaster management or vice versa

All countries have emergency management legislation and related regulations and plans which, to varying degrees of detail and compulsion, define key infrastructure providers as “lifeline utilities,” “critical Infrastructure,” or similar and require organizations falling under this definition to be able to continue to operate during and after an emergency. This has been spelled out more clearly in the New Zealand context than some other, where a wide range of life utilities are required to have planned and resourced their organizations, facilities, and services to be able to continue to operate to the fullest extent possible during and after emergencies.

Lifeline utility coordination is a function defined usually carried out in response coordination centers under the respective incident management system’s *operations* function. Lifeline

utility coordination is most likely to be activated at both regional and national levels, rather than local levels.

The Lifeline Utility Coordinator (LUC) tends to be a non-statutory regional and national emergency management position responsible for coordinating lifeline utilities on behalf of the response controller or director during emergency response and the recovery manager throughout recovery activities.

The roles are assigned before an emergency occurs and activated if required during an emergency.

Summary

In summary, responses to significant earthquakes are challenging and complex. This entry has explored the key aspects of earthquake response that are particularly pertinent to the context of earthquake engineering. Although responses to virtually all emergencies and disaster start and finish with the affected communities, formal leadership and coordination of responses are vitally important for effective response to an earthquake event. When significant earthquakes strike, the challenges for those in positions of leadership or who are responsible for response coordination are many and varied. This is due in large part to the reality that affected communities will be mounting their own responses while official responses are still regrouping and reestablishing communications. The very nature of damaging quakes makes them some of the most difficult hazards to manage responses to, as the sudden and widespread impacts significantly affect the ability of response organizations to deliver their services more than other hazards tend to.

Empirical Fragility

Ioanna Ioannou and Tiziana Rossetto
Department of Civil, Environmental and
Geomatic Engineering, University College
London, London, UK

Synonyms

Damage probability matrices; Empirical fragility assessment; Empirical seismic fragility; Fragility curves

Introduction

The seismic fragility of assets, i.e., buildings and lifelines, is defined as the likelihood of damage to the assets from future earthquake events. Fragility is an important component of seismic risk assessment and is key to the determination of the seismic vulnerability of the exposed assets (i.e., likelihood of economic loss, life loss, or downtime in future earthquake events). Relationships for defining fragility are typically classified into the categories of empirical, analytical, judgment-based, or hybrid according to the type of data used in their determination. Empirical fragility relationships are based on the statistical analysis of post-earthquake observations of the seismic damage sustained by exposed assets. A number of sources for post-earthquake asset damage or loss data are available (e.g., surveys commissioned by authorities in order to assess structural safety or evaluate cost of repair for insurance, tax reductions, or government aid distribution purposes) and the reliability of empirical relationships is heavily dependent on the quality and size of the adopted observational databases. Analytical and judgment-based fragility relationships are based on the interpretation of the results of numerical analyses and expert opinion of the behavior of assets in earthquakes, respectively. Hybrid fragility relationships combine two or more of these data sources in their definition.

Empirical Fragility, Fig. 1 Illustration of (a) a column of a DPM for intensity im , (b) fragility curves corresponding to $n = 3$ damage states for the same building class

Empirical fragility is typically expressed either in terms of damage probability matrices (DPMs) that express the probability of a class of assets with similar attributes suffering given damage states under specified ground motion or a continuous relationship between a measure of damage (damage state) and ground motion or ground failure intensity (see Fig. 1) for a specified asset class. The continuous functions are overwhelmingly expressed in terms of fragility curves. These curves are obtained by fitting a statistical model to the post-earthquake damage observations. The two expressions of empirical fragility are related as depicted in Fig. 1b, where it can be noted that the distances between two successive fragility curves for a given intensity measure level relate to the corresponding values in the damage probability matrix.

Empirical fragility assessment was firstly introduced by Whitman et al. (1973), who constructed DPMs for tall buildings by relating an 8-state discrete damage scale to loss data collected from 1,240 questionnaires in the aftermath of the 1971 San Fernando earthquake, USA. Since then, approximately 89 studies are seen in the published literature (i.e., academic journals, conference proceedings, reports, and book chapters) to have focused on the development of empirical fragility functions for the global building and

lifeline inventory. Many of these studies include fragility functions for multiple classes of assets.

Figure 2 shows a steady increase in the number of studies on empirical fragility of buildings over the past 40 years. Recently, the Global Earthquake Project (GEM) (Rossetto et al. 2013) compiled a database of empirical fragility functions for the global building inventory. GEM's database consists of 175 empirical fragility functions constructed for the global building inventory. Figure 3 shows that almost half of existing functions have been constructed for the European building stock. Most empirical functions are based on post-earthquake observations collected from a single earthquake event (e.g., Braga et al. 1982). Few exceptions exist of functions based on databases from multiple global (e.g., Spence et al. 1991; Rossetto and Elnashai 2003) or national (e.g., Rota et al. 2008) events. Recently, GEM (Rossetto et al. 2014) built on the state-of-the-art research and proposed new guidelines for the construction of empirical fragility curves from single or multiple earthquake event databases. Within these guidelines procedures are proposed for the assessment of the quality of the post-earthquake observation databases and for fragility relationships to be derived using statistical approaches of increasing complexity according to the characteristics of the adopted observational databases.

Empirical Fragility,

Fig. 2 Studies focused on empirical fragility assessment of buildings and lifeline networks published in the last four decades (Data sourced from the compendium of empirical fragility functions of buildings in GEM (Rossetto et al. 2013) and Syner-G (Pitilakis et al. 2014))

Empirical Fragility,

Fig. 3 Country of origin of existing fragility functions for buildings

Empirical fragility research for lifelines peaked in the 1990s. In the context of the empirical fragility literature, fragility curves and DPMs for lifelines have mainly been derived for use in transportation (e.g., railway, roadway, or harbors) and utility (e.g., gas and oil, potable water and wastewater, or electric power) networks. Existing studies identify the main components of each network (see Fig. 4) and assess their empirical fragility from post-earthquake data using similar procedures to those used in the empirical fragility assessment of buildings. The fragility of each component is then used in order to estimate the overall fragility of the network (see ► [Seismic Vulnerability Assessment: Lifelines](#)). Recently, Syner-G (2014) compiled a global database of fragility functions for the components of the global lifeline inventory presented in Fig. 4.

Empirical Fragility Assessment Framework

The general framework for constructing fragility functions for a class of assets is presented in Fig. 5. According to this framework, the construction of empirical fragility functions requires the collection of three types of post-earthquake data: data on the level of seismic damage suffered by the assets, the characteristics of these assets, and the level of ground motion or ground failure intensity the assets were exposed to. A statistical model is commonly fitted to the data to generate the mean fragility function and its confidence bounds. The following sections provide a brief overview of each component of the empirical fragility framework.

Elements of Transportation Networks: • Railway Tracks (1) • Road Pavement (1) • Bridges (5) • Tunnels (2) • Embankments (1) • Quay walls (1) • Cargo handling and storage components (1) • Fuel facilities (1) • Waterfront structures (1)	Elements of Utility Networks: • Water Source (1) • Potable-Water Treatment Plant (2) • Waste-Water Treatment Plant (2) • Pumping Plant (2) • Canals (1) • Pipes (20) • Storage Tanks (4) • Electric power substations (3) • Electric micro-components (7) • Electric power grid (1)

Empirical Fragility, Fig. 5 Empirical fragility assessment framework

Post-Earthquake Surveys

The reliability of an empirical fragility function is strongly dependent on the quantity and quality of post-earthquake damage observations used for its construction. Ideally post-earthquake damage assessment data should be available for all the assets within the desired asset class that were exposed to the earthquake event. If observations on all the assets are not available, at least a statistically significant representative sample of the exposed assets should be used. In practice, databases of post-earthquake damage observations rarely include the total number of exposed assets and may be very small in size or subject to bias. In general, the quality and quantity of these databases depend on why they were carried out, how, and by whom. The four main types of surveys that have to date provided post-earthquake damage observations for empirical fragility studies are described

in Table 1. Such surveys are typically commissioned by authorities or conducted by reconnaissance organizations and are briefly discussed here. Authorities often commission a post-earthquake “rapid” survey, which aims to assess the safety of assets. These surveys commonly adopt damage scales consisting of three limit states (such as in ATC-20 2005 in the USA). However, some may only adopt two broad damage states (i.e., damaged and undamaged, or safe and unsafe), grouping together a wide range of seismic damage levels. Such surveys aim to assess all exposed assets in an affected location and commonly do not capture many details of the characteristics of the assets (i.e., may only record the construction material of a building but not its height and age). Due to the rapid assessment often from the street by small groups of perhaps inexperienced engineers, these databases are also

Empirical Fragility, Table 1 Main survey types and their main properties

Survey method	Typical sample sizes	Typical building classes	Typical no. of damage states	Reliability of observations	Typical issues
Rapid surveys	Large	All buildings	2–3	Low	Safety not damage evaluations. Misclassification errors
Detailed “engineering” surveys	Large to small	Detailed Classes	4–6	High	Possibility of under-coverage errors
Surveys by reconnaissance teams	Very small	Detailed Classes	4–6	High	Possibility under-coverage errors or very small samples
Remotely sensed	Very large	All buildings	2–3	Low	Only collapsed or very heavy damaged states may be reliable. Misclassification errors

commonly found to suffer from two main errors, namely, misclassification and nonresponse errors. The former type of errors is introduced when the safety level of a building is different from the actual damage suffered by the assets. For example, a building sustained substantial damage and should be classified as “unsafe” but the survey form indicates it is “safe.” This error can potentially have a significant impact on fragility functions (see Ioannou and Rossetto 2013). Nonresponse errors are instead introduced when the forms used for collecting the survey data are incomplete. For example, the location or address of surveyed assets is missing from the form. The mechanism of the missing data determines how this error is treated. For example, due to the speed of “rapid;” surveys, some boxes in the survey forms are left blank completely at random. In this case, the forms with incomplete data can be removed from the database. This leads to, sometimes substantially, smaller sample sizes. By contrast, the missingness mechanism could depend on the missing observations. For example, the safety assessment on the form is left blank, if the building is classified as safe. In this case, the knowledge of this mechanism is essential in order to effectively reduce the bias introduced by this nonresponse error.

“Rapid” surveys can be followed by detailed “engineering” surveys. These surveys collect detailed data concerning the characteristics of assets and damage levels. Although the

“engineering” surveys cover large number of assets, they tend to concentrate on the damaged assets, ignoring the undamaged ones. This practice introduces an error, termed under-coverage, in the database. This error introduces a bias in the database, which can be reduced by the use of data from alternative sources when the source of under-coverage error is known. For example, if it is known that only damaged buildings have been surveyed, it may be reasonable to estimate the number of undamaged buildings from census data.

Reconnaissance surveys are conducted by small teams of highly experienced engineers. These surveys are therefore of high quality but often suffer from small sample sizes, given the limited time the reconnaissance teams spend in the field and the small areas surveyed.

Finally, surveys based on remote sensing techniques have been recently introduced for the empirical fragility assessment of buildings. Of note is the recent establishment of the Virtual Disaster Viewer (Bevington et al. 2010), supported by several international institutions that provide images and a forum for experts to interpret damage from satellite images. The subsequent GEO-CAN initiative (Ghosh et al. 2011) also brought together experts from all over the world to interpret damage in the 2010 Haiti and 2011 Christchurch, New Zealand earthquakes. These surveys have the ability to gather data for large sample sizes of the assets of interest. However, as they are based on observations of

changes to building roofs and plans from comparison of pre- and post-earthquake aerial images, they are unable to distinguish between building classes and are only able to assess the collapse (and to lesser extent heavy damage) state in buildings. Consequently, the inaccuracies involved in the assessment of the damage lead to substantial misclassification errors for the non-collapse damage states (Booth et al. 2011).

Damage Assessment

The seismic damage suffered by assets is typically expressed in terms of a damage scale with n number of discrete qualitative states. The damage states can be defined in terms of structural and nonstructural damage levels. They vary from no damage to collapse and are often considered to be mutually exclusive and collectively exhaustive. The scales, adopted in the literature, vary in the number of damage states and the level of detail in the description of damage for each damage state according to the needs of the survey.

Damage scales with $n = 4\text{--}6$ states are mostly adopted for the classification of damage observed in buildings and lifeline components. Some of the most commonly used damage scales for post-earthquake damage surveys for buildings are the European Macroseismic Scale (Grünthal 1998) and its predecessor the Medvedev-Sponheuer-Karnik scale (Medvedev 1977). For lifelines, HAZUS proposes qualitative damage scales for most components, which are observed to be similar to those for buildings. Syner-G (2014), instead, recently proposed damage scales expressed in terms of operational states, which describe whether or not the component functions. Despite the presence of well-established damage scales, many studies adopt national damage assessment scales (e.g., AeDES in Italy) or bespoke scales. This wealth of damage scales is problematic when databases or fragility functions need to be combined or compared. This problem has been recently addressed by Rossetto (2014) who, building on the work of Hill and Rossetto (2008), has drawn equivalence tables between the various damage scales found in the literature.

In the construction of empirical fragility functions, ideally a damage scale should contain 3 to

6 damage states. Fragility functions are constructed for each damage state, and thus there needs to be a significant number of observations for each damage state in order to ensure the reliability of the corresponding empirical function. In practice, a balance needs to be reached between the number of damage states and the number of observations. In other words, for the same sample size, the fewer the damage states, the more data in each, but the wider the damage states, the less informative the fragility functions in the context of loss estimation. Furthermore, due to the rarity of large earthquake events near urban areas, higher damage states (e.g., collapse) tend to contain few observations, and hence fragility functions constructed for these states may be less reliable than the functions corresponding to less severe damage states.

A notable exception to the above discrete definition concerns the pipes, whose levels of damage are measured in terms of the number of repairs per mile.

Characteristics of Assets

Assets affected by similar intensity measure levels often perform very differently. These differences can be, at least partially, attributed to their unique structural characteristics. Empirical fragility assessment requires the availability of statistically significant sample sizes in order to construct reliable fragility functions. Thus, classes of assets are often determined based on the characteristics that significantly influence their seismic performance. In theory, the more detailed the class, the more homogenous the group of assets and the smaller the variation in seismic response. However, in practice narrowly defined classes often result in small sample sizes. A careful balance is, therefore, needed between level of detail in the class definition and sample size.

For example, the structural characteristics of buildings, which influence their seismic performance, are well documented (e.g., FEMA - 547 2007) and include (but are not limited to):

- Construction material
- Lateral load resisting system (e.g., moment-resisting frame, shear wall, etc.)

- Layout in plan and elevation
- Presence of irregularities (e.g., soft storey, short column, etc.)
- Seismic design code used (i.e., capacity design, level of structural detailing)
- Height of structure
- Weight of structure
- Redundancy of structure
- Type and amount of strengthening intervention

Existing studies overwhelmingly classify buildings according to their structural characteristics. The crudest classes are based on the construction material. The most detailed classes include the construction material, height, structural system, and design code. Most empirical functions, however, are based on classes that use only two structural characteristics, namely, the construction material as well as (in descending order of frequency) age, structural system, or height. Despite the existence of various building classification systems (e.g., adopted by HAZUS (FEMA 1999) or PAGER (Porter et al. 2008)), these are not commonly adhered to by existing studies; rather, bespoke building classes are defined.

Similar rules apply for the classification of the components of the lifeline networks. For instance, bridges are mostly classified according to their construction material and their structural system.

Intensity of Earthquake-Induced Hazards

Assets located in seismic areas are exposed to two main classes of earthquake-induced hazards, namely, ground shaking and ground failure (i.e., liquefaction, landslides and surface fault rupture, tsunami, and fire). Empirical fragility of buildings is typically expressed in terms of ground shaking, which is found to be the main cause of damage to buildings (Bird and Bommer 2004). By contrast, both hazards are found to cause damage to the lifelines, which are distributed over extensive areas.

With regard to ground shaking, three main groups of intensity measures have been adopted in past empirical fragility studies and a brief

introduction to these is presented in what follows (a comprehensive review of these measures can be found in Rossetto et al 2013). In the early empirical fragility studies for buildings, popular measures of ground motion intensity were macroseismic intensities, such as the Modified Mercalli Intensity scale or the Medvedev-Sponheuer-Karnik scale. Macroseismic intensities are discrete scales and a value of macroseismic intensity is assigned to an area based on the observed effects of the earthquake on the area (e.g., the level of observed damage to buildings and experiences of people affected by the event). However, the criteria defining the earthquake effects are often worded ambiguously, and their interpretation is subjective leading to potentially large discrepancies in their evaluation by different groups. A continuous alternative to the discrete macroseismic measures is the parameterless scale of seismic intensity (PSI), proposed by Spence et al. (1991).

A different approach for the selection of ground motion intensity measures has been promoted by the current seismic risk assessment framework, where it is important to decouple the uncertainties associated with the seismic demand from those associated with the structural fragility. Recent empirical fragility studies therefore adopt ground motion parameters that can be evaluated from ground motion recordings, e.g., peak or spectral values of ground motion. However, due to the scarcity of strong ground motion recording stations and the need to quantify the ground motion parameters at each asset site, in practice ground motion parameter values are obtained from ground motion prediction equations. Due to the large number of ground motion prediction equations available and due to its traditional use in the definition of design loads for structures and seismic hazard maps, peak ground acceleration (PGA) is the main parameter used to represent ground motion intensity in empirical fragility studies of buildings and elements of lifeline networks. However, it is well known that PGA does not correlate well with observed damage (especially for ductile structures or severe damage states). In engineering terms, PGA is related

to the dynamic loads imposed on very stiff structures and, therefore, may not be adequate for the characterization of seismic demand in medium or high rise building populations. Peak ground velocity (PGV) and peak ground displacement (PGD) are more representative of the seismic demand on structures of intermediate and long natural period of vibration than PGA, respectively. Both PGV and PGD are generally calculated through the integration of accelerograms and may be sensitive to both the record noise content and the filtering process.

The peak ordinates of a ground motion record, however, are unable to capture features of the earthquake record, such as frequency content, duration, or number of cycles, which affect the response of a structure and its consequent damage and loss. Hence, in an attempt to better capture the influence of accelerogram frequency content, more recent empirical fragility studies have favored the use of response spectrum-based parameters as measures of ground motion intensity. These parameters include the spectral acceleration for the fundamental period and less often the spectral displacement.

Ground failure (particularly liquefaction, lateral spreading, and fault rupture) is expressed in terms of permanent ground deformation, which can be measured laterally, vertically (i.e., settlement), or volumetrically. Vertical settlement can be measured in terms of total settlement or differential settlement, which has greater implications for damage to structures and lifelines. There are currently no standardized parameters for describing permanent ground deformation, though Bird et al. (2006) summarize some more common parameters, which vary in terms of input requirements and methodological approach. There have been few empirical damage observation studies related to ground failure incidents and therefore fewer studies on fragility estimation to these hazards (e.g., Tokimatsu et al. 1994).

Statistical Model Fitting Procedures

Having collected post-earthquake data, the empirical fragility assessment concludes with

Empirical Fragility, Table 2 Example of a damage probability matrix for a theoretical construction class

Bins of intensity (e.g., PGA in g)	0.02–0.04		0.04–0.06	
	Counts	DPM (%)	Counts	DPM (%)
No damage	100	50	60	30
Slight	80	40	90	45
Moderate	18	9	45	23
Collapse	2	1	5	3
<i>Total</i>	<i>200</i>	<i>100</i>	<i>200</i>	<i>100</i>

the construction of fragility functions for classes of assets. Empirical fragility functions are essentially stochastic relationships, which relate the damage to an asset class with the corresponding ground motion or ground failure intensity. These relationships can be discrete (i.e., DPMs) or continuous (e.g., fragility curves).

Damage Probability Matrices

In its simplest form, empirical fragility is expressed in terms of a discrete function. Its construction requires the aggregation of the damage data for assets of a given class into bins of similar ground motion or ground failure intensity levels. The counts of buildings suffering given levels of damage for an examined bin, normalized by the total number of buildings in this bin, provide the values of the damage probability matrix (see Table 2).

Continuous Fragility Functions

Fragility functions are typically constructed by fitting a statistical model to the available post-earthquake data. Practically, a statistical model consists of two components: a random and a systematic component. The random component expresses the probability distribution of the response variable (e.g., the counts of buildings reaching or exceeding a damage state) given the explanatory variable (i.e., the ground motion or ground failure intensity). The systematic component expresses the mean response as a function of the explanatory variable, in other words the mean empirical fragility function.

There are two main types of continuous fragility functions, described below, depending on whether the examined assets can be considered point-like or line-like. The difference between the two types is that point-like assets occupy a relatively small area where the intensity is assumed constant for each asset. Point-like assets include standard buildings and all components of lifeline networks presented in Fig. 4, with the exception of pipes which are considered line-like assets.

Fragility Functions for Point-Like Assets

Fragility functions for point-like assets are expressed in terms of fragility curves. In the literature, fragility curves are typically constructed by fitting parametric statistical models to the available data. A parametric model represents a family of probability distributions of the response conditioned on the explanatory variable defined by a small number of parameters. The most commonly used approach, which is described below, is to fit a generalized linear model to the data (e.g., Shinozuka et al. 2000). These models are based on strong assumptions, which, when they are satisfied, lead to reliable predictions. Nonparametric models have also been adopted for the construction of empirical fragility curves, but they suffer from the danger of over-fitting, especially if the data are aggregated in only small number of bins of ground motion or ground failure intensities. These models include the generalized additive models (see Rossetto et al. 2014) and the Gaussian Kernel Smoothers (see Noh et al. 2013).

The generalized linear model is based on the underlying assumption that the seismic response of each asset is a Bernoulli trial, i.e., the response is equal to 1 if the sustained damage is $DS \geq ds_i$ and 0 otherwise. Given that the damage data typically are aggregated in bins of similar ground motion or ground failure intensity, the response is considered to follow a binomial distribution for intensity level, im :

$$N_i | im \sim \binom{n}{n_i} \mu_i^{n_i} [1 - \mu_i]^{n-n_i} \quad (1)$$

where N_i are the counts of assets that have been damaged to a level equal or exceeding a predetermined damage state, $DS \geq ds_i$; n is the total number of assets in a bin associated with intensity level im . This distribution is essentially the fragility curve and is characterized by the mean response for given intensity, μ_i , as:

$$g(\mu_i) = \begin{cases} \theta_{1i} \ln(im) + \theta_{0i} & (.1) \\ \theta_{1i} im + \theta_{0i} & (.2) \end{cases} \quad (2)$$

where $g(\cdot)$ is termed the link function and relates the mean response with the intensity or the natural logarithm of the intensity. The link function can be expressed in three forms:

$$g(\mu_i) = \begin{cases} \Phi^{-1}(\mu_i) & \text{probit} & (.1) \\ \log\left(\frac{\mu_i}{1 - \mu_i}\right) & \text{logit} & (.2) \\ \log[\log(1 - \mu_i)] & \text{complementary loglog} & (.3) \end{cases} \quad (3)$$

The first two functions presented in Eq. 3 are symmetrical functions, and the last one is asymmetrical.

The parameters of the generalized linear models can be estimated by two procedures. In the first procedure, the parameters are estimated by maximizing the likelihood function through an iterative least squares algorithm, as:

$$\begin{aligned} \theta_i^{opt} &= \text{maxarg}[L(\theta_i)] \\ &= \text{maxarg} \left[\prod_{j=1}^{m_{bins}} \binom{n_j}{n_{ij}} \mu_{ij}^{n_{ij}} [1 - \mu_{ij}]^{n_j - n_{ij}} \right] \end{aligned} \quad (4)$$

In the second approach, a Bayesian regression analysis (e.g., Straub and Der Kiureghian 2008; Ioannou and Rossetto 2013) is adopted in order to take into account prior information regarding the model's parameters, θ , especially when the available number of observations is small. Prior information is obtained from existing fragility functions or independent post-earthquake data of similar groups of assets. In addition, this

analysis allows for the increase in the model's complexity by explicitly accounting for the measurement error in the intensity measure levels (e.g., Straub and Der Kiureghian 2008) or the misclassification of the damage (e.g., Ioannou and Rossetto 2013). The aim of the Bayesian analysis is the estimation of the posterior distribution of the model parameters, $f(\theta|y, x)$, from Bayes' theorem:

$$f(\theta|y, x) = \frac{L(\theta; y, x)f(\theta)}{f(y)} = \frac{L(\theta; y, x)f(\theta)}{\int L(\theta; y, x)f(\theta)d\theta} \quad (5)$$

where $f(\theta)$ is the prior distribution of the regression parameters accounting for existing prior knowledge.

Fragility Functions for Line-Like Assets The continuous fragility functions, constructed for groups of line-like assets, measure the damage in terms of the number of repairs per unit length (termed repair rate) of these assets for given levels of intensity. The repair rate (RR) is related to the intensity through the use of a linear (i.e., the parameters of the model are linearly combined) or nonlinear (i.e., the parameters of the model are nonlinearly combined) statistical model. These models can be expressed in different forms:

$$\begin{aligned} &RR|im \sim Normal(\mu(im), \sigma), \text{ where } \mu(im) = a im + b \\ &\text{or} \\ &\log_{10}(RR|im) \sim Normal(\mu(im), \sigma), \text{ where } \mu(im) = a im + b \\ &\text{or} \\ &\ln(RR|im) \sim Normal(\mu(im), \sigma), \text{ where } \mu(im) = \ln(a) + b \ln(im) \end{aligned} \quad (6)$$

where σ is the standard deviation, which is constant for each intensity level; $\mu(im)$ is the mean repair rate or the lognormal repair rate or the natural logarithm of this rate, which is expressed as a function of the intensity. The model is fit to the available data using a least squares method.

The number of breaks or leaks for the total length (L) of the line-like asset is considered to follow a Poisson distribution. Therefore, if we assume that the examined asset fails if there is at least one break, then the probability of failure for the total length of the asset is obtained, as:

$$\begin{aligned} &P(\text{line-like asset segment fails}) \\ &= 1 - P(\text{No failure}) = 1 - e^{-RR \cdot L} \end{aligned} \quad (7)$$

Summary

The empirical seismic fragility of an asset (i.e., buildings or components of lifeline networks) expresses the potential for its damage in future earthquake events. Empirical fragility is assessed by the statistical analysis of post-earthquake

observations on damage to assets, their characteristics, and the ground motion or ground failure they are subjected to. This typically includes the fitting of a parametric statistical model to the observational data. The reliability of empirical fragility functions depends on two main conditions: firstly, on the quality of the post-earthquake observational data and whether the database includes statistically representative samples of the exposed assets and, secondly, on whether the assumptions on which the selected statistical model is based upon are satisfied. To date, studies struggle to satisfy both of these conditions.

Introduction

A knowledge of the seismic ground motion is essential to understanding the earthquake behavior of structures. The basic data of earthquake engineering are the records of ground acceleration during moderate-to-strong earthquakes (Housner 1970). Acceleration time series (also known as accelerograms and strong-motion records) are the acceleration of the ground sampled many dozens of times per second in three mutually orthogonal directions. For decades, the reference ground motion for earthquake engineers was the renowned El Centro accelerogram, recorded in California in 1940. It was only after the Loma Prieta (1989), Northridge (1994), and Kobe (1995) earthquakes that hundreds of strong-motion records were made available worldwide through databases accessible from the Internet (Pacor et al. 2011). The huge increase of accelerograms highlights the significant variability of ground motion, depending on several factors related to size and focal mechanism of the

event, distance and position of the recording site with respect to the source, properties of the propagation medium, and geological condition underlying the recording station.

In Fig. 1 examples of accelerometric and velocimetric time series recorded close to the source at sites located on rock and stiff soil (STS and AQA stations) and intermediate distances on soft sites (MDN and CESV) are plotted. Each time series is characterized by peculiar features, such as (i) presence of surface waves (MDN); (ii) impulsive behavior (STS); (iii) low-frequency velocity pulse (AQA); and (iv) absence of low-frequency waves (CESV).

The ability to characterize strong ground motion and capture the main features that can potentially cause damage to engineering and geotechnical structures is one of the main inputs in development methods to mitigate seismic risk.

In this chapter, several topics related to accelerometric data are illustrated, including (i) issues related to instrumental characteristics; (ii) evaluation of data quality; (iii) processing

procedures to compute acceleration, velocity, and displacement time series for use for seismic hazard studies and engineering applications; and (iv) definition of the main intensity measures computed from the accelerometric time series.

Analog and Digital Recording Instruments

Accelerometric signals are recorded by two types of instruments (Trifunac and Todorovska 2001):

- Analog accelerographs are optical-mechanical devices that produce traces of the ground acceleration on film or paper. These were in use since the early 1930s to the end of the twentieth century, although the 2004 Parkfield earthquake was recorded principally on such instruments. They have several disadvantages: (i) they operate on standby and recording is triggered by a specific acceleration threshold, so they do not preserve the pre- and post-event time series; (ii) the natural frequency of transducers is generally limited to about 25 Hz or even less, limiting the usable frequency band; and (iii) if numerical analyses are planned, in order to be able to use the recording, it is necessary to process the film and then digitize the traces.
- Digital accelerographs are in general use since the 1980s and record ground motion in continuous mode in digital media (e.g., cassettes or solid-state memory), and, even when they operate on standby, they preserve the pre- and post-event portions of the time series. The precision of the recorded ground motion depends on the instrument settings, such as the digitizer's dynamic range, sampling rate and sensor full scale. The analog-to-digital conversion (ADC) process can produce offsets in the acceleration baseline if the ground motion is slowly varying compared with the quantization level of the digitization (Boore 2003).

Figure 2 shows an example of the same event recorded by an analog and a digital instrument

that were colocated. In this particular example, the analog instrument was triggered by the S-waves.

Strong-Motion Data Processing

It is important for users of strong-motion data to understand that digitized accelerograms are not exact reproductions of the ground motion, as they contain noise of various origins at both high and low frequencies. The purpose of the signal processing is the estimation and the removal of the noise present in the record, in order to evaluate reliable ground motion for standard and specific applications. Generally it is not possible to identify the “ideal” processing for an individual record, as assumptions always need to be made and a certain degree of subjectivity is involved. Boore and Bommer (2005) provide an extensive overview of techniques for processing strong-motion data and the consequences of applying different approaches, from the perspective of engineering applications. Special cases, such as the processing of near-source strong-motion recordings are discussed by Graves (2004).

Data Quality and Data Processing

The first step before data processing is a quality check of the records. The user can decide, depending on the specific application, if the record should be disregarded or not before further processing.

Douglas (2003) reports the features that identify strong-motion recordings as poor quality (see Table I of his paper), based on an analysis of the records of the European Strong-Motion Database (Ambraseys et al. 2004). Based on these results, the most relevant features include (i) insufficient digitizer resolution; (ii) S-wave trigger, which can be a concern for recordings from analog instruments (Fig. 2); (iii) insufficient sampling rate; (iv) early termination during coda; (v) spikes (Fig. 3); and (vi) presence of multiple baselines.

Some of these characteristics, so-called non-standard errors, do not correspond to the usual

Engineering Characterization of Earthquake Ground Motions, Fig. 2 Aftershock of the Umbria-Marche seismic sequence, central Italy (event 1997-10-0705:09:56

UTC); acceleration time series at the analog station NCR (*top*); acceleration time series at the digital station NCR2 (*bottom*) (Source <http://itaca.mi.ingv.it>)

Engineering Characterization of Earthquake Ground Motions, Fig. 3 Example of spurious spikes (raw record of event 1998-01-1301:49:16 UTC at SELW) (Source <http://itaca.mi.ingv.it>)

sources of noise and they can often be visually identified and removed prior to further processing.

As an example, spurious “spikes” in the digitized record can be replaced with the mean of the accelerations of the data points on both sides of the spike. Another problem encountered with both analog and digital accelerograms are distortions and shifts in the baseline (Fig. 4), which result in unphysical velocities and displacements (Boore 2003). Boore and Bommer (2005) detail

an approach to compensate for these problems consisting in the use of baseline adjustments (Graizer 1979; Iwan et al. 1985; Boore 2001; Boore et al. 2002; Paolucci et al. 2008). In particular, the use of baseline-fitting techniques can sometimes recover permanent ground displacements from accelerograms.

Filtering

The process of filtering generally involves the removal of most of the signal at frequencies

Engineering Characterization of Earthquake Ground Motions, Fig. 4 Example of baseline shift and its effect on the velocity time series (event 1979-05-21 12:36:40 UTC recorded at NCR) (Source <http://itaca.mi.ingv.it>)

where the Fourier amplitude spectrum (FAS) shows a low signal-to-noise ratio. Therefore, the critical issue for end users is to appreciate the record limitations after certain frequencies have been removed.

Filters can be applied in the frequency or time domains; exactly the same results should be obtained in both cases. While the choice of filter type is not crucial, the way in which the filter is applied to the accelerograms is very important. The fundamental choice is between causal and acausal filtering, where the latter does not produce any phase distortion in the signal, whereas causal filters do result in phase shifts in the record. The influence of causal and acausal filters on both elastic and inelastic response spectra has been investigated by Boore and Akkar (2003), who found that both elastic and inelastic response spectra computed from causally filtered accelerations can be sensitive to the choice of filter corner periods even for oscillator periods much shorter than the filter's corner periods. Finally, Bazzurro et al. (2005) performed a statistical study on the influence of various signal-processing techniques used for low-cut filtering ground motion records on both elastic and inelastic response spectra.

Low Frequency Noise Removal

The impact of low-frequency noise (<1 Hz) can have strong influence on strong-motion intensity measures such as ground velocities, displacements, and response spectral ordinates, and therefore most of the studies have investigated the effects of low-cut (high-pass) filters.

The low-frequency cutoff, the lowest frequency for which the data are reliable in terms of signal-to-noise ratio, can be determined in several ways: (i) comparison of the FAS of the record with that of a model of the noise obtained from the pre-event memory for digital records, for example; (ii) judgment of the frequency where the record FAS deviates from the tendency to decay in proportion to the reciprocal of the frequency squared, based on a seismological model of the radiated energy (omega-square model, Brune 1970); or (iii) visual inspection of the velocity and displacement time series obtained by double integration of the filtered acceleration.

Figure 5 shows the effect of low-cut filtering. A digital record is filtered using two different low-cut frequencies. The lowest frequency generates a low signal-to-noise ratio and leads to unrealistic velocity and displacement time series (gray boxes highlight the differences).

Engineering Characterization of Earthquake Ground Motions, Fig. 5 Example of low-cut filtering (event 2010-01-1213:35:45UTC recorded at AQUA). *Left:*

low-cut equal to 0.01 Hz; *right:* low-cut = 0.2 Hz (ACC, acceleration; VEL, velocity; DIS, displacement)

Acausal low-cut filters are generally preferred (Boore 2005) and, in order to achieve the zero phase shift, they need to start prior to the beginning of the record and finish after the end of the accelerogram, which can be accomplished by adding points of zero amplitude, known as pads, to the two ends of the record. The length of the pads depends on the filter frequency and its order (Boore 2005).

After filtering, the processed accelerograms are integrated once to obtain velocities and again to obtain displacement time series. They can also be used to obtain other intensity measures (see below).

High-Cut Filters

Ground motion at periods of less than roughly 0.05 s is generally only relevant to particular engineering problems, such as the design and analysis of nonstructural elements, equipment, and pipework (e.g., in nuclear power plants).

Before applying high-cut (low-pass) filters one should consider that the sampling rate determines the upper usable frequency, termed the Nyquist frequency, equal to $(1/2\Delta t)$ where Δt is the sampling interval. High-cut filter applied at

frequencies greater than the Nyquist will have no effect on the record.

Douglas and Boore (2011) give an exhaustive overview of the approaches and effects of high-cut filtering. While low-cut filters have large influence on ground motion intensity measures, high-cut filtering is sometimes even not necessary and accelerometric response spectra can often be used up to frequencies much larger than the applied high-cut corner used to remove the noise. As in the case of low-cut filters, acausal high-cut filters are generally preferred.

Applicability of Processed Data

The user should be aware that different corrected versions of the same record may be distributed in different strong-motion databases. Foti and Paolucci (2012) studied the influence of correction procedures by performing numerical simulations (seismic behavior of a diaphragm wall). The results show large differences, especially in terms of displacements, which is a parameter of particular relevance when dealing with performance based design.

Sometimes database providers distribute processed accelerograms that are incompatible

with the provided velocity and displacement time series because they apply additional processing to reduce noise that is still present in the record. In other cases, time series are not compatible because the pads added for the application of the filter are removed. The consequence of their removal is to weaken the effect of the filter and this can result in offsets and trends in the base-lines of the velocity and displacements obtained by integration.

In order to avoid the latter effects the correct initial conditions in the pad-stripped time series have to be used when computing displacements, velocities, and linear oscillator response. Another way of ensuring compatibility is to post-process the pad-stripped acceleration time series.

Boore et al. (2012) examined the post-processing adopted for two databases, ITACA (Italian Accelerometric Archive, Paolucci et al. 2011; Pacor et al. 2011) and PEER NGA (Pacific Earthquake Engineering Research Center–Next Generation Attenuation), and demonstrated that any biases and distortions are small for the vast majority of the records of the two databases, so data can be used with confidence.

Strong-Motion Intensity Measures

For many engineering and scientific applications, it is useful to describe the seismic ground motion in terms of a few simple parameters instead of the entire waveform. These parameters are evaluated both in the time and frequency domains, each of them capturing some features of the recorded accelerograms.

Time-Domain Parameters

The most common parameter is the *peak ground acceleration*, PGA, which denotes the maximum ground acceleration (absolute value) observed on the accelerometric time series, usually evaluated for each component of the ground motion. It can be evaluated directly either from raw or corrected signals, since PGAs change slightly with respect to the processing procedure.

Similarly, the *peak ground velocity*, PGV, and *peak ground displacement*, PGD, are defined.

Differently from PGA, PGV and PGD can be read only after processing the accelerometric record, and their values are strictly related to the band-pass filtering, especially in case of PGD, which strongly depends on the low-cut corner frequency.

Although the PGA is widely used in earthquake engineering, as it is directly related to the inertia force, it poorly characterizes the ground motion, as demonstrated in Fig. 6. Records with the same PGA can have completely different features in the other ground motion parameters, depending on the magnitude of the event, the source-to-site distance and the geological condition of the site where the recording station is located.

A preliminary estimation of the frequency content of the records may be inferred by the PGA/PGV ratio (Zhu et al. 1988; Sawada et al. 1992; Kwon and Elnashai 2006). Low PGA/PGV ratios generally indicate earthquakes with low predominant frequencies, broader response spectra, and longer duration.

The *duration* of the accelerogram is a parameter used to identify the portion of record in which ground motion amplitude can potentially cause damage to engineering and geotechnical structures.

Several definitions are proposed (Bommer and Martinez-Pereira 1999), as many different meanings can be attached to “duration.” The most commonly used are as follows:

- (a) *Bracketed duration*, introduced by Bolt (1973): a threshold is fixed, typically 0.05 g or 0.1 g, above which it is deemed that the motion has relevance for engineering purposes; the duration is the time interval between the first and the last exceedance of this value.
- (b) *Significant duration*, introduced by Trifunac and Brady (1975) on the basis of the study by Husid (1967), is defined as the time interval over which the integral of the square of the ground acceleration (Husid plot) is within a given range of its total value. Usually this range is between 5 % and 95 % or between 5 % and 75 %. An example of the two

Engineering Characterization of Earthquake Ground Motions, Fig. 6 Left: examples of accelerometric waveforms having PGAs in the range 105–112 cm/s², event 2012-05-29 11:00:25 UTC, Italy, recorded at T0800 (deep alluvium); event 1990-12-13 00:24:26 UTC, Italy, recorded at SRT (rock); event 1997-11-12 15:24:23 UTC, Italy, recorded at NCR2 (shallow alluvium); event 2002-

02-03 07:11:29 UTC, Turkey, recorded at 0301 (alluvium). Middle and right: velocity and displacement waveforms derived from the accelerometric signals in the left panel. For each waveforms, the peak values (Max) is reported (Source <http://itaca.mi.ingv.it> and Turkish National Strong Motion Program http://kyhdata.deprem.gov.tr/2K/kyhdata_v4.php)

Engineering Characterization of Earthquake Ground Motions, Fig. 7 Accelerometric waveform (bottom) and corresponding Husid plot (top) at station Aqv (event 2009-04-06 01:32:32 UTC, Italy). The values of bracketed duration (bottom) and significant duration (top) are also reported

definitions of duration is presented in Fig. 7 for the L'Aquila, Italy, earthquake (M_w 6.3) recorded at Aqv. As marked in this figure, the time interval between 5 % and 95 % of the Husid plot represents the significant duration of the record.

The *Arias intensity* is directly related to the definition of the significant duration. It is an integral parameter adopted to measure the severity of ground motion and it has been found to be a useful measure for thresholds of shaking that trigger landslides (Jibson et al. 1998).

Arias intensity is defined as

$$I_A = \frac{\pi}{2g} \int_0^{T_d} a^2(t) dt \quad (1)$$

where $a(t)$ is the acceleration at time t and g the gravity acceleration, the Arias intensity is the maximum value of this function and T_d is the time corresponding to the end of the accelerogram. Arias intensity has the dimension of a velocity.

The root mean square acceleration is a parameter used in the past to measure the radiated energy. It is defined as the square root of the mean of the squared acceleration computed for a specific time interval of the record (i.e., $\Delta T = T_2 - T_1$):

$$a_{rms} = \left\{ \frac{1}{T_2 - T_1} \int_{T_1}^{T_2} a^2(t) dt \right\}^{1/2} \quad (2)$$

This parameter strongly depends on the choice of the duration and, for this reason, is of limited use inside the engineering community.

Frequency Domain Parameters

Fourier Spectra

A measure of the frequency content of the accelerogram can be obtained through the Fourier transform.

The Fourier transform of an accelerogram $a(t)$ with total duration T_d is defined as follows:

$$F(f) = \int_0^{T_d} a(t) e^{-i2\pi ft} dt \quad (3)$$

Since $F(f)$ is a complex function, it can be expressed as $F(f) = A(f) - iB(f)$

where

$$\begin{aligned} A(f) &= \int_0^{T_d} a(t) \cos(2\pi ft) dt; \quad B(f) \\ &= \int_0^{T_d} a(t) \sin(2\pi ft) dt \end{aligned} \quad (4)$$

Of particular significance to engineering seismologists is the Fourier amplitude spectrum, $FAS(f)$, defined by

$$FAS(f) = \sqrt{A^2 + B^2} \quad (5)$$

The FAS is widely used to investigate the ground motion amplitude and energy content at different frequencies.

Acceleration FAS are often analyzed to decompose the observed ground motion into the spectral functions describing the source of the event, the propagation from the source to the site, and the site effect (Castro et al. 1990; Bindi et al. 2009). Acceleration FAS are also used to estimate the empirical site response, through the Standard Spectral Ratio (SSR; Tucker and King 1984), based on the ratio between the FAS between the horizontal (or vertical) components of the selected site and a reference site or the Horizontal to Vertical Spectral Ratio (HVSr; Lermo and Chávez-García 1993) based on the ratio of the FAS between the horizontal and vertical component of a single station, that provides reliable estimates of the fundamental frequency when the site effects are mainly controlled by resonance phenomena.

Records of large earthquakes and/or from soft sites usually feature larger motions at low frequencies than records of small events and/or from rock sites. Figure 8 displays the Fourier spectrum amplitude of two acceleration signals recorded at AQV for two events of magnitude M 5.1 and M 6.3, located at the same distance from the station.

Response Spectra

For engineering purposes, the most important parameter to represent seismic motion is the response spectrum, in terms of relative displacement, relative velocity or absolute acceleration. The response spectrum is defined as the maximum response amplitude of a single-degree-of-freedom (SDOF) system, subject to the acceleration time series, as a function of the system period T_n . The response spectrum can be calculated for

Engineering Characterization of Earthquake Ground Motions, Fig. 8 Fourier amplitude spectra (FAS) for the accelerometric waveforms recorded at AQV station for event 2009-04-07, M 5.1 (Italy) at epicentral distance $R = 5.8$ km and event 2009-04-06, M 6.3 (Italy) at epicentral distance $R = 5.1$ km

E

Engineering Characterization of Earthquake Ground Motions, Fig. 9 Acceleration response spectra (SA) (*left*), velocity response spectra (SV) (*center*) and displacement response spectra (SD) (*right*) for the

accelerometric time series of Fig. 6. Different axis scales are adopted to highlight the different spectral shapes associated to the signals

different damping ratios, ξ (usually a value equal to 5 % of the critical damping is assumed, which is roughly applicable to most structures).

The maximum amplitude of the response is obtained by integrating the equation of motion of the SDOF system:

$$\ddot{x}(t) = -\omega_n^2 y(t) - 2\xi\omega_n^2 \dot{y}(t) \tag{6}$$

where

$y(t)$ and $\dot{y}(t)$ are the relative displacement and velocity of the oscillator with respect to the ground, $\ddot{x}(t)$ is the absolute acceleration of the oscillator, given by $\ddot{y}(t) + a(t)$; $\omega_n = \frac{2\pi}{T_n}$ is the

natural circular frequency of the oscillator. When acceleration, velocity, or displacement is considered, the following definitions are introduced:

Displacement spectrum (relative)	$SD(T_n, \xi) = \max_t y(t) $
Velocity spectrum (relative)	$SV(T_n, \xi) = \max_t \dot{y}(t) $
Acceleration spectrum (absolute)	$SA(T_n, \xi) = \max_t \ddot{x}(t) $

The acceleration response spectra are very common among earthquake engineers since the maximum absolute value of $\ddot{x}$, when multiplied by m , represents the maximum force imposed on the structure.

Engineering Characterization of Earthquake Ground Motions, Table 1 Strong-motion parameters inferred from accelerometric records plotted in Fig. 6

	PGA [cm/s ²]	PGV [cm/s]	PGD [cm]	AI [cm/s]	HI [cm]	T90 [s]
U301	113	13.0	2.60	17.0	43.7	16.6
NCR2	103	2.1	0.06	2.5	2.1	1.5
T0800	104	5.1	0.35	5.3	11.1	11.6
SRT	106	7.0	1.20	5.8	23.1	12.7

Figure 9 shows the acceleration, SA, velocity, SV, and displacement, SD, response spectra (5 % damping) for the acceleration time series shown in Fig. 6.

At period $T = 0$ s, the spectral displacement and velocity are zero and the spectral acceleration equals the PGA; this is the reason for which the PGA is largely adopted in seismic codes to anchor design spectra. On the other hand, when T approaches infinity, SA approaches zero and SD approaches PGD.

The pseudo-acceleration and pseudo-velocity spectra are also widely used in practice. They are defined as a function of the displacement spectrum as follows:

pseudo-acceleration spectrum

$$: PSA(T_n, \xi) = \left(\frac{2\pi}{T_n}\right)^2 SD(T_n, \xi) \quad (7)$$

pseudo-velocity spectrum:

$$PSV(T_n, \xi) = \left(\frac{2\pi}{T_n}\right) SD(T_n, \xi) \quad (8)$$

The response spectra (SA or PSA) of the processed ground accelerations are usually published alongside the accelerograms by various recording agencies.

The pseudo-spectra well approximate the absolute response spectra, in case of small damping values and intermediate and high frequencies, while they exactly match the absolute response spectra in case of an undamped oscillator. Pseudo-spectra and spectra differ at very low frequencies, since SV tends to PGV and PSV tends to zero (Hudson 1979).

A ground motion parameter related to PSV is the Housner intensity (HI) or spectral intensity

(SI) defined as the area under the pseudo-velocity response spectrum (PSV) over the period range 0.1–2.0 s (Housner 1952):

$$SI(\xi) = \int_{0.1}^{2.5} PSV(T, \xi) dT \quad (9)$$

This parameter measures the severity of seismic motion in terms of potential damage, since the majority of structures have a fundamental period of vibration in the range 0.1–2.5 s. Dimensionally, the Housner intensity is a displacement.

Table 1 lists the main strong-motion parameters relative to the records plotted in Fig. 6.

Public Sources of Strong-Motion Records

Various governmental and local agencies, as well as many universities and research institutes, operate strong-motion networks. Depending on the agency, accelerometric data are distributed in various ways (real time or triggered by an event, raw or processed, with basic metadata or revised metadata). The main sources of strong-motion data (worldwide, European, national) for engineering application are discussed in detail in this paragraph. Other sources are listed in Table 2.

Worldwide Databases

The major source of US strong-motion data is the California Strong Motion Instrumentation Program (CSMIP). The Centre for Engineering Strong Motion Data (CESMD <http://www.strongmotioncenter.org/>) distributes processed and unprocessed strong-motion data from US and major international earthquakes.

The COSMOS Virtual Data Center (<http://www.cosmos-eq.org/VDC/index.html>) is a web portal to access strong ground motion records. It distributes records from the United States and 14 contributing countries for use by the engineering and scientific communities. It contains flexible search methods, including map-based, parameter-entry, and earthquake- and station-based searches. Display and download options allow users to view data in multiple contexts, extract and download data parameters, and download data files in convenient formats.

The Pacific Earthquake Engineering Research Center (PEER) database (http://peer.berkeley.edu/peer_ground_motion_database) has been created for engineering applications (e.g., development of ground motion prediction equations in the framework of the Next Generation Attenuation, NGA, program). The latest version of the PEER Ground Motion Database contains 3,182 three-component recordings of

104 shallow crustal earthquakes worldwide compiled from over 1,000 stations, extensive metadata (including different distance measures, various site characterizations and earthquake source data) with corrections to the information contained in the original databases. The web interface provides tools for searching, selecting, and downloading ground motion data.

European/Pan-European Databases

The European Strong-Motion Database (http://www.isesd.hi.is/ESD_Local/frameset.htm) contains more than 3,000 uniformly processed and formatted waveforms. Each waveform is associated to earthquake and station parameters. The user can search the database and databank interactively and download selected strong-motion records and associated parameters.

WebDc (<http://eida.gfz-potsdam.de/webdc3/>) is a portal to the European Integrated Data Archive (EIDA) infrastructure, which is a

distributed data center that aims to securely archive seismic waveform data gathered by European research infrastructures. Through the EIDA portal, the user can request real-time data streams from permanent networks that are mostly acquired over the internet and are immediately accessible as continuous data streams by SeedLink in real time. Raw seismological data (waveform) and station lists (Dataless SEED, Inventory XML) can be obtained from different data centers spread across Europe.

National Databases

1. *Italy*. The Italian Accelerometric Archive (ITACA, <http://itaca.mi.ingv.it>) contains about 7,500 three-component processed waveforms generated by about 1,200 earthquakes with magnitudes greater than 3, in the time span 1972–2013. Corrected and uncorrected time series and response spectra are available from the download pages, where the parameters of interest can be set and specific events, stations, waveforms, and their metadata can be retrieved. Quasi real-time Italian strong-motion data recorded by the two national accelerometric networks (RSN, managed by the National Institute of Geophysics and Volcanology, INGV and RAN, operated by Department of Civil Protection, DPC) can be accessed at ISMD (<http://ismd.mi.ingv.it/>) and MOT1 (<http://www.mot1.it/randownload/EN/index.php>).
2. *Turkey*. The strong-motion database of Turkey (http://kyhdata.deprem.gov.tr/2K/kyhdata_v4.php) contains about 10,000 (processed and unprocessed) waveforms recorded, from 1976 to the present, by the network operated by the Prime Ministry for Disaster and Emergency Management. Corrected and uncorrected time series and response spectra are available from the download pages, where events, stations, and waveforms can be searched with respect to basic parameters.
3. *Greece*. The Greek strong-motion database from 1973 to 1999 is contained in the Hellenic Accelerogram Database, HEAD (<http://www.itsak.gr/en/head>). The dataset includes 677 three-component records associated to 319 earthquakes, obtained from 117 strong-motion stations. For the major earthquakes after 2000, an additional web page has been created (<http://www.itsak.gr/en/db/data/sm/after2000>). Waveforms can be searched specifying event date and time and station code. Corrected and uncorrected time series and response spectra are available from the download pages.
4. *Japan*. Japanese records are available at <http://www.kyoshin.bosai.go.jp/>. K-NET (Kyoshin network) is a strong-motion seismograph network that consists of more than 1,000 observation stations distributed roughly every 20 km. K-NET is operated by the National Research Institute for Earth Science and Disaster Prevention (NIED) since 1996. At each K-NET station, a seismograph is installed on the ground surface. KiK-net (Kiban Kyoshin network) is a strong-motion seismograph network that consists of pairs of seismographs installed in a borehole and on the ground surface deployed at roughly 700 locations. The strong-motion data recorded by K-NET and KiK-net are transmitted in real-time to the NIED data management center and can be downloaded by users. The soil conditions at K-NET stations and the geological and geophysical data derived from drilling boreholes at KiK-net stations are available.

Codes to Select Spectrum-Compatible Strong-Motion Data

The strong-motion databases are also employed to select records that match a target spectrum and that can represent a response spectrum for a scenario event computed from a ground motion prediction equation or which may be derived from probabilistic seismic hazard analysis and presented as a uniform hazard spectrum (UHS) or which may be developed from building code provisions. The selected records, conveniently scaled to fit the target spectrum, are then used as input into numerical simulations for structural analysis and response site study. Several methods

Engineering Characterization of Earthquake Ground Motions, Table 3 List of some computer codes to select spectrum-compatible records

Name	Reference	Main characteristics
SigmaSpectra	Kottke and Rathje (2008)	It selects suites of earthquake ground motions from a library of ground motions such that the median of the suite matches a target response spectrum at all defined periods, then scales the suite such that the standard deviation agrees with the target standard deviation
	http://nees.org/resources/sigmaspectrav	The library of ground motions and the spectrum should be supplied by users
REXEL/REXEL-DISP	Iervolino et al. (2009); Smerzini and Paolucci (2013); Smerzini et al. (2013)	REXEL allows to define the design spectra according to the Eurocode 8, the new Italian Building Code (NTC08) or user defined. The strong-motion datasets contained in REXEL come from ESMD, ITACA and SIMBAD (Selected Input Motions for Displacement-Based Assessment and Design, Smerzini and Paolucci 2013)
	http://wpagina.unina.it/iuniervo/	REXEL-DISP allows to select suites of natural accelerograms compatible with <i>displacement spectra</i> of NTC08, EC8, or user defined. The records library is SIMBAD
CMS – Conditional Mean Spectrum	Baker (2011); Jayaram et al. (2011)	CSM allows one to compute the expected response spectrum associated with a target spectral acceleration (S_a) value at a single period; the records selection is based on PEER database; records compatible with predicted response spectra from NGA model (also as a conditional spectrum) can be directly selected from the web-based tool in the PEER database
ASCONA	Corigliano et al. (2012)	It allows to select records which are compatible both with acceleration and displacement response spectra The strong-motion dataset is extracted from NGA dataset, ITACA, ESMD, and K-net databases, and it only includes waveforms recorded on rock site condition
RSPMatch09	Al Atik and Abrahamson (2010)	It performs time-domain spectral matching by adding adjustment wavelets to an initial acceleration time series to generate a modified time series whose response spectrum is compatible with a specified target response spectrum
	http://nees.org/resources/rpsmatch09	The library of ground motions and the spectrum should be supplied by users

and computer codes are proposed in literature to this aim, some of them together their characteristics are reported in Table 3; other information can be found in the section devoted to this topic.

Summary

Accelerometric time series recorded during moderate and strong seismic events are fundamental for earthquake engineers and engineering

seismologists since they are immediately usable to estimate damage. Furthermore, from accelerometric waveforms, several strong-motion parameters can be inferred, such as peak values, spectral ordinates, measures of the frequency content, and the shaking duration, which are fundamental elements for seismic design and evaluation of the seismic response of structural and geotechnical systems.

This chapter presents engineering characteristics of strong ground motion. In section “[Analog](#)

and Digital Recording Instruments,” issues related to the instrumental characteristics of the analog and digital accelerometers are described.

In section “[Strong-Motion Data Processing](#),” an overview on the processing of strong-motion data is presented focusing on the evaluation of data quality and on the procedures that are commonly adopted to remove high- and low-frequency noise in the signals. In section “[Strong-Motion Intensity Measures](#),” the main strong-motion parameters in the time and frequency domains and their characteristics and applications are illustrated. These parameters include peak values (acceleration, velocity, and displacement), integral parameters (Arias and Housner intensities) and Fourier and elastic response spectra. Finally, in section “[Public Sources of Strong-Motion Records](#),” the main worldwide, European and national public strong-motion databases are listed, together with a short description of their content in terms of strong-motion data and associated information.

Equivalent Static Analysis of Structures Subjected to Seismic Actions

Nouredine Bourahla

Civil Engineering Department, University Saâd Dahlab, Blida, Algeria

Synonyms

Equivalent seismic force; Lateral seismic force; Seismic base shear; Seismic design; Seismic force distribution

Definition

The equivalent static lateral force method is a simplified technique to substitute the effect of dynamic loading of an expected earthquake by a static force distributed laterally on a structure for design purposes. The total applied seismic force V is generally evaluated in two horizontal directions parallel to the main axes of the building (Fig. 1). It assumes that the building responds in its fundamental lateral mode. For this to be true, the building must be low rise and must be fairly symmetric to avoid torsional movement under ground motions. The structure must be able to resist effects caused by seismic forces in either direction, but not in both directions simultaneously.

Introduction

Loading due to earthquake upon a given structure comes from ground motions, defined as a variation in the ground accelerations with time, resulting in inertial forces acting on the masses of the structure. These forces depend on the characteristics of the structure, the earthquake, and other factors such as distance from the fault and geology of the site.

To design a structure capable to withstand the effect of an earthquake, the forces upon the structure must be first specified. However, due to the fact that each earthquake can lead to different ground motions accelerations even within a same site, the resulting forces which will affect the structure within a given prone seismic region cannot be specified with precision. As a result, a realistic estimate of such forces is important for the safety and the cost-efficiency of a structure.

The simplest way to do so is using the “equivalent static lateral force method,” even though its uses are limited by various conditions, related to the site and the structure itself and which are acknowledged and detailed below. Within this method, a seismic coefficient is applied to the mass of the structure to produce the lateral force that is approximately equivalent in effect to the dynamic loading of the expected earthquake.

Historical Background

The origin of the equivalent static lateral force method goes back to the early twentieth century, where the idea of a lateral design force V proportional to the building's weight was first developed following the Messina-Reggio earthquake of December 28, 1908. This relationship can be written as $F = CW$, where C is a lateral force coefficient, expressed as some percentage of the gravity. The first official implementation of this criterion was the specification, $C = 10\%$ of the gravity, issued as a part of the 1924 Japanese Urban Building Law Enforcement Regulations in response to the destruction caused by the great 1923 Kanto earthquake (Elnashai 2002; Reitherman 2006).

Some destructive earthquakes motivated several communities to adopt codes with different percentages for the seismic coefficient C . Later the equivalent static lateral force was based on the seismic zone factor, building period, building weight, and lateral resisting system type. These factors are still being refined and used to estimate the equivalent lateral force (Mitchell et al. 2010).

Equivalent Static Analysis of Structures Subjected to Seismic Actions, Fig. 1 Equivalent lateral shear force along two orthogonal axes

Domain of Application

The equivalent lateral static force may be applied to buildings in which the response is not significantly affected by contributions from modes of vibration higher than the fundamental mode in each principal direction and meeting the criteria for building height, horizontal and vertical regularities. The use of this method is also restricted with respect to the seismic zones. This suggests that this method is limited to structures having regular configurations with continuous seismic-force-resisting elements and a relatively uniform distribution of mass and stiffness. The main irregularities that most seismic codes use as criteria to classify the building configuration include the following aspects (FEMA 749 2010):

Horizontal Irregularities

- Torsional irregularity – This condition exists when the distribution of vertical elements of the seismic-force-resisting system within a story is such that when the building is pushed to the side by a lateral force, it will tend to twist as well as to deflect horizontally.

- Reentrant corner irregularity – This is a geometric condition that occurs when a building with an approximately rectangular plan shape has a missing corner or when a building is formed by multiple connecting wings.
- Diaphragm discontinuity irregularity – This occurs when a structure's floor or roof has a large open area as can occur in buildings with large atriums.
- Out-of-plane offset irregularity – This occurs when the vertical elements of the seismic-force-resisting system are not aligned vertically from story to story.
- Nonparallel systems irregularity – This occurs when the structure's seismic-force-resisting does not include a series of frames or walls that are oriented at approximately 90° angles with each other.

Vertical Irregularities

- Stiffness soft-story irregularity – This occurs when the stiffness of one story is substantially less than that of the stories above.
- Weight/mass irregularity – This exists when the weight of the structure at one level is

substantially in excess to the one at the levels immediately above or below it.

- In-plane discontinuity irregularity – This occurs when the vertical elements of a structure's seismic-force-resisting system such as walls or braced frames do not align vertically within a given line of framing or the frame or the wall has a significant setback.

The classification of a structure as “regular” or “irregular” affects several aspects of the design and analysis such as the permission to use the equivalent lateral force, the behavior factor, and the type of models for analysis.

Equivalent Lateral Static Force Procedure

The equivalent lateral force procedure provides a simple way to incorporate the effects of inelastic dynamic response into a linear static analysis. This procedure is useful in preliminary design of all structures and is allowed for final design of the vast majority of structures. As stated before, the procedure is valid only for structures without significant discontinuities in mass and stiffness along the height, where the dominant response to ground motions is in the horizontal direction without significant torsion (FEMA 750 2007). The equivalent static analysis procedure involves the following steps:

- Calculation of the total lateral seismic force V
- Vertical distribution of seismic forces along the height of the structure
- Horizontal distribution of the level forces across the width and breadth of the structure
- Calculation of the additional forces from the inherent and accidental torsion
- Determination of the drift, overturning moment, and P-Delta effect

Calculation of the Total Lateral Seismic Force V

Although the equivalent lateral static force is a code-dependent relationship, the general formula is expressed as the product of the effective

seismic weight W and a response coefficient C_S . It can be written as follows:

$$V = C_S W \quad (1)$$

where

W is the effective seismic weight. It includes the total *dead load* above the foundation or above the top of a rigid basement and applicable portions of other loads (*live load* and *snow*). For instance, in areas used for permanent storage such as library shelves, fixed equipments, etc., the total floor *live load* should be applicable. In areas used for housing or administrative purposes, only a percentage (20–30 %) of the floor *live load* should be applicable.

C_S is the seismic response coefficient expressed as a spectral pseudoacceleration, in g units, which depends on several factors to account for the seismic zone, the structure period, the local soil conditions, the inelastic performance of the lateral resisting system, and the nature of the structure's occupancy and use.

It might help to understand this formula to go back to the basic relationship between the force and the acceleration, which is $F = Ma$.

Seismic Response Coefficient C_S

As noted previously, the seismic response coefficient C_S depends on several factors and can be written in different manner according to the seismic codes. In all cases the controlling parameters are the same:

$$C_S = f(S_a, I, R, T, T_S, T_L) \quad (2)$$

S_a : design ground acceleration

I : importance factor

R : lateral resisting behavior factor (reduction or modification factor)

T : structure fundamental period

T_S and T_L : soil/seismicity depending factors (periods)

Before going into the details of each parameter, it is useful to know what data is necessary to obtain the seismic response coefficient. The following items refer to the information needed to obtain the seismic response coefficient:

Equivalent Static Analysis of Structures Subjected to Seismic Actions, Fig. 2 Seismic response coefficient spectral shape

E

- The location where the building will be constructed to determine the seismic zone (seismic hazard).
- The soil conditions must be known to determine the Site Class (T_S and T_L), and this requires an investigation that includes boring and removing soil samples at various depths.
- The structure fundamental period T , calculated or estimated using empirical formulae.
- The lateral resisting system type, to determine the modification factor R .
- The structure use, including consideration of the number of people who would be affected by the structure failure and the need to use the structure for its intended purpose after an earthquake. These information are necessary to determine the importance or occupancy class (I) of the building.

Design Ground Acceleration (S_a)

The design ground motion is one of the primary factors used to determine the required seismic resistance (strength) of structures and supported nonstructural components. In many seismic codes the design ground acceleration is used as a product of an acceleration factor which depends on the seismic zone and a dynamic amplification factor which depends on the soil class and the

fundamental period of the structure. Recently, the design ground motion is defined by an acceleration response spectrum characterized by three ranges as shown on Fig. 2.

AB represents the maximum constant acceleration part of the spectrum and lays in the range $0.0 < T < T_S$. T_S is a function of seismicity and site (in some codes it depends only on the site conditions). Depending on the seismic code, T_S may be as low as 0.15 s for low-hazard regions on very hard soil conditions or as high as 0.9 s in high-hazard regions on very soft soil conditions.

BC represents the constant velocity part of the spectrum in the range $T_S < T < T_L$. In this region, the seismic response coefficient is inversely proportional to the period, and the pseudovelocity (pseudoacceleration divided by circular frequency, ω) is constant. T_L the long-period transition ranges from 3 to 4 s in some codes.

CD represents the constant displacement part of the spectrum for $T > T_L$. In this region C_S is inversely proportional to T^2 . This part only affects tall and flexible structures.

Importance Factor

The importance class or factor depends on the occupancy category of the building. Hence, essential facilities such as hospitals and fire and

police stations are designed for seismic forces greater than normal. In this way, such structures are expected to resist an earthquake and be able to be functional in the post-earthquake period. Buildings containing certain highly toxic substances must also be designed to meet these higher standards. Similarly, high-occupancy buildings that represent a substantial hazard to human life (schools, health care facilities, and stadiums) must be designed for seismic forces less than vital category and greater than normal. Finally, for constructions which are not subject to human occupancy with insignificant economic loss can be designed for seismic forces less than normal. The importance factor is used either as an independent factor or combined with the seismicity and site parameters to categorize structures according to the seismic risk they could pose (seismic design category concept) (IBC 2012; FEMA 750 2007). In certain codes the importance factor may increase the seismic forces for vital facilities up to 1.5 times the normal seismic forces.

Site Class (Ground Conditions)

To take into account the site effect on the estimation of the equivalent lateral static force, the concept of Site Class is used to categorize common soil conditions into broad classes to which typical ground motion attenuation and amplification effects are assigned. Site Class is determined based on the average properties of the soil within a certain depth (30 m) from the ground surface. Most of the seismic codes specify 4–6 categories of soils ranging from hard, competent rock materials to very soft, loose materials. For each category are assigned the parameters T_S and T_L which define the transition points on the acceleration design spectrum.

Behavior (Modification) Factor R

The behavior factor or the response modification factor R , which is determined by the type of lateral load resisting system used, is a measure of the system's ability to accommodate earthquake loads and absorb energy without collapse. The resistance and energy-dissipation capacity to be assigned to the structure are related to the

extent to which its nonlinear response is to be exploited. In operational terms, such balance between resistance and energy-dissipation capacity is characterized by the values of the behavior factor R and the associated ductility classification. As a limiting case, for the design of structures classified as non-dissipative, no account is taken of any hysteretic energy dissipation and the value of the behavior factor may not be taken, in general, as being greater than the value of 1.5. For dissipative structures, the value of the behavior factor can be taken greater than this limiting value in order to account for the hysteretic energy dissipation that mainly occurs in specifically designed zones, called dissipative zones or critical regions (EN 1998–1 2004). In general, seismic codes provide tables listing different lateral resisting systems with associated values of R .

In terms of calculation, instead of performing an explicit inelastic structural analysis in design, the capacity of the structure to dissipate energy, through mainly ductile behavior of its elements, is taken into account by performing an elastic analysis based on a lateral force reduced by a factor R (Fig. 3). Thus, the behavior factor R is an approximation of the ratio of the seismic forces that the structure would experience if its response was completely elastic to the seismic forces that may be used in the design, with a conventional elastic analysis model.

Fundamental Period Determination

The fundamental period of the structure, T , is used to determine the design ground acceleration and in some codes to establish the distribution of the shear along the height of the structure. The fundamental period T can be determined from a rational analysis using the structural properties and deformational characteristics of the resisting elements or, alternatively, using an approximate empirical relationship. In most seismic codes, the calculated period by analysis is limited by a coefficient times the approximate (empirical) period. This period limit prevents the use of unusually low base shear when using the equivalent static lateral force for design of

Equivalent Static Analysis of Structures Subjected to Seismic Actions, Fig. 3 Reduction factor R based on equivalent elastic plastic deformation

buildings (or computational models) that are overly flexible (FEMA 750 2007).

The most common empirical expression used to estimate the fundamental period is given by:

$$T = C_t h^x \quad (3)$$

where C_t and x are coefficients which depend on the type of lateral resisting system and h is the height of the building, in m, from the foundation or from the top of a rigid basement.

Vertical Distribution of the Equivalent Static Force

Once the total base shear is known, it is used to determine the forces on the various building elements. For multistory buildings, the forces must be distributed according to the fundamental mode which can be simulated by an inverted force triangle varying from zero at the base to a maximum at the top (Fig. 4). With this simplified approach, it is assumed that there is uniform mass distribution and equal floor heights, but the codes do provide for variations, where the force at a given level is proportional to the height

h times the lumped mass W at that height according to Eq. 4. The sum of the loads at each level equals the total base shear. Also note that while the greatest force is at the top of the building, the shear increases from zero at the top to its maximum at the base. Each floor shear is successively added to the sum from above.

To account for higher modes participation in tall buildings that do not have a uniform triangular distribution, some codes require that an additional force F_t be applied at the top of the building. The lateral force induced at any level h_i can be determined from the following equation:

$$F_i = \frac{W_i h_i}{\sum_{j=1}^n W_j h_j} (V - F_t) \quad (4)$$

where

F_i : lateral force applied at level i

V : total lateral static force (Eq. 1)

F_t : additional force to be applied at the top of tall buildings to account for higher mode participation

W_i, W_j : lumped story masses at level i and j

Equivalent Static Analysis of Structures Subjected to Seismic Actions, Fig. 4 Vertical distribution of the lateral static force

h_i, h_j : heights of the masses $W_i W_j$ above the level of application of the seismic action (foundation or top of a rigid basement)

n : number of lumped masses along the height of the building (the number of floors in multistory buildings)

Alternatively, to take account of higher modes, some codes prescribed the following distribution formula:

$$F_i = \frac{W_i h_i^k}{\sum_{j=1}^n W_j h_j^k} V \quad (5)$$

The superscript k has a value of unity for structures with a fundamental period (T) less than or equal to 0.5 s, has a value of 2 for structures with a fundamental period greater than or equal to 2.5 s, and has a value that is linearly

interpolated from these values for structures with a fundamental period that falls between these values (FEMA 750 2007).

Horizontal Distribution of the Equivalent Static Force

Within the context of an elastic analysis, the distribution of lateral forces to various seismic-force-resisting elements depends on the type, geometric arrangement, and vertical extents of the resisting elements and on the shape and flexibility of the floor diaphragms. In a simplified manner, the forces F_i applied at each level shall be distributed to the various elements of the vertical lateral force-resisting system in proportion to their rigidities, considering that the diaphragm is rigid and the lateral force-resisting system is

Equivalent Static Analysis of Structures Subjected to Seismic Actions,

Fig. 5 Horizontal distribution of the lateral force at floor (level) i

composed of several lines parallel to the direction of the seismic force (Fig. 5). The distribution expression can be written as follows:

$$F_{ij} = \frac{K_{ij}}{\sum_{k=1}^{nk} K_{ik}} F_i \quad (6)$$

F_{ij} : force acting on the lateral force-resisting line j at a floor level i

nk : number of lateral force-resisting elements (lines)

K_{ij} , K_{ik} : story stiffness of the lateral force-resisting element (line) k and j at level i

F_i : seismic force at floor (level) i

The design shall include the torsional moment, resulting from the eccentricities of the location of the masses and the centers of rigidities. In addition to the torsional moment, the design also should include accidental torsional moments. For rigid diagrams, the mass at each level is assumed to be displaced from the calculated center of mass in each direction a distance equal to 5 % or 10 % of the building dimension at that level perpendicular to the direction of the force under consideration. The torsional moment creates torsional displacement (twisting about the

vertical axis) and will be resisted by the lateral force-resisting elements (lines) in proportion to their rigidities and their distances from the center of rigidity (Fig. 6).

The additional force resulting from the torsional moment is given by the following expression:

$$F_{\theta j} = \frac{K_{ij} r_j}{\sum_{k=1}^{nk} K_{ik} r_k^2} F_i e \quad (7)$$

$F_{\theta j}$: force resulting from the torsional moment acting on the lateral force-resisting element (line) j

F_i : seismic force at floor (level) i

e : total eccentricity

$K_{ij} K_{ik}$: story stiffness of the lateral force-resisting element (line) k and j at level i

$r_k r_j$: distance from the axes of the force-resisting element (line) k and j to the rigidity center C_r

nk : number of lateral force-resisting elements (lines)

It should be noted that in seismic design when the force on a vertical element caused by the eccentricity acts in the same direction as that

Equivalent Static Analysis of Structures Subjected to Seismic Actions, Fig. 6 Torsional moment effect due to eccentric lateral force for rigid diaphragm

caused by the lateral load directly (lateral force-resisting elements located on the flexible side), they must be added. However, when the torsional force acts in the opposite direction (rigid side), it will not be subtracted.

Minimum Base Shear Limit

In many seismic codes, the equivalent static lateral force V is used as a reference value of the total seismic design base shear. For instance, the base shear calculated using the modal response spectrum analysis should not be less than 80 % or 90 % of the equivalent lateral base shear. This minimum base shear is provided because the computed period of vibration may be the result of an overly flexible (incorrect) analytical model.

Drift Story

Seismic design of structures must ensure that the anticipated lateral deflection in response to

earthquake shaking does not exceed acceptable levels. The lateral deflection is expressed in terms of the inter-story drift which is a measure of how much one floor or roof level displaces under the lateral force relative to the floor level immediately below. It is typically presented as a ratio of the difference in deflection between two adjacent floors divided by the height of the story that separates the floors. The determination of the story drifts has to be based on the application of the design seismic forces to a mathematical model of the physical structure. The model shall include the stiffness and strength of all elements that are significant to the distribution of forces and deformations in the structure.

Since the forces used for design include the response modification coefficient, R , the resulting displacements are too small and must be amplified. Most of the seismic codes account for this difference, by multiplying the elastic displacements by the modification coefficient R or a deflection amplification factor which is typically similar to R , but a little less than,

the R coefficient. Therefore, the deflection at a level I is given by

$$\delta_I = R.15em\delta_{ei} \quad (8)$$

The inter-story deflection becomes

$$\Delta_I = \delta_i - \delta_{i-1} \quad (9)$$

The drift is also an important consideration for structures constructed in close proximity to one another. In response to strong ground shaking, adjacent structures can hit one another, an effect known as pounding. Pounding can induce very high forces in a structure at the area of impact and has been known to be the cause of collapse of some structures. Therefore, the seismic codes require that structures be set far enough away from one another and from property lines to avoid pounding.

Overtaking Moment and P-Delta Effects

Because the inertial force created by an earthquake represented by the equivalent lateral force acts through the center of mass of a building, there is a tendency for the moment created by this force acting above the base to overturn the structure. This overturning force must be counteracted by stabilizing load. Normally, the dead weight of the building, also acting through the center of mass, is sufficient to resist the overturning force, but it must always be checked.

P-Delta or second-order effect is an instability phenomenon that results from the simultaneous actions of the lateral force and dead load. Seismic provisions require an evaluation of the structure stability under the anticipated lateral deflection by calculating a “stability coefficient” θ for each story. The value of θ is given by the following expression:

$$\theta = \frac{P_i \Delta_i}{V_i h_i} \quad (10)$$

In this formula, P_i is the weight of the structure above the story being evaluated, Δ_i is the design

story drift determined using Eq. 9, V_i is the sum of the lateral seismic design forces above the story, and h_i is the story height. If the calculated value of θ at each story is less than or equal to 0.1, the structure is considered to have adequate stiffness and strength to provide stability. If the value of θ exceeds 0.1, the lateral force analysis must include explicit consideration of P-Delta effects. These effects are an amplification of forces that occurs in structures when they undergo large lateral deflection. A limiting value for θ ($\theta_{\max}$) varying between 0.2 and 0.3 is generally prescribed. If the structure exceeds this limiting value, it is considered potentially unstable and must be redesigned unless nonlinear response history analysis is used to demonstrate that the structure is adequate.

Summary

The equivalent static lateral force method is a simplified technique to substitute the effect of dynamic loading of an expected earthquake by a static force distributed laterally on a structure for design purposes. The total applied seismic force V is generally evaluated in two horizontal directions parallel to the main axes of the building.

The equivalent static analysis procedure involves the following steps:

- Calculation of the total lateral seismic force V which depends on the seismic zone (design ground acceleration), the building importance, the soil conditions, the fundamental period of the structure, the lateral force-resisting system, and the effective seismic weight (dead and part or entire of live load)
- Determination of the vertical distribution of seismic forces along the height of the structure, where the force at a given level is proportional to the height h times the lumped mass m at that height (simplified method)
- Considering a horizontal distribution of the level forces to the various elements of the vertical lateral force-resisting system in proportion to their rigidities, considering that the diaphragm is rigid

- Calculation of the additional forces from the inherent and accidental torsion to be added to the forces resulting from the horizontal distribution of the level forces
- Determination of the drift, overturning moment, and P-Delta effect that are the direct results of the action of the lateral seismic forces

Introduction

Large earthquakes are known to have significant damage potential in urban regions. Recently all over the world, efforts are made toward reduction of future probable damages. The first step in damage mitigation is the estimation of expected damage levels in buildings that are subjected to earthquakes with different intensities. Due to the inherent uncertainties involved in the analyses, estimation of seismic damage rates must be handled within a probabilistic framework.

To assess the damage rates under different shaking levels, “seismic damage” needs to be quantified and measured in a standard manner. The most common approach to quantify seismic damage rates is to perform fragility analyses. Fragility is defined as the probability of a system reaching a limit state as a function of seismic intensity levels (Kafalı and Grigouri 2004). Fragility analyses are generally carried out with one of the following five alternative approaches: empirical, analytical, subjective, experimental, and hybrid methods. The results of such damage probability assessment analyses can be expressed in terms of fragility curves or damage probability matrices. Fragility curves are continuous curves that state the cumulative damage rates whereas damage probability matrices

Estimation of Potential Seismic Damage in Urban Areas, Table 1 A typical damage probability matrix

Damage state (DS)	Central damage ratio (%)	MMI = V	MMI = VI	MMI = VII	MMI = VIII	MMI = IX
None	0	Damage state probabilities, Pr(DS,I)				
Light	5					
Moderate	30					
Heavy	70					
Collapse	100					

express the same information in terms of discrete damage probabilities for a particular intensity level.

Empirical method is based on the fundamental idea that similar type of structures experiences comparable damage rates under earthquakes. It involves analysis of empirical data collected in post-earthquake surveys. In the analytical method, in order to estimate the limit states of the structure, the seismic performance under a given ground motion level is assessed through detailed time history analysis or other simplified methods. Subjective method includes expert opinions for the assessment of the damage probabilities under various levels of shaking intensities. Experts are requested to give their opinions on the level of the damage based on their relevant experience on seismic damage assessment. It is also possible to generate fragility curves based on the experimental data that has been obtained through a series of tests. Finally, hybrid method involves a combination of the previously described approaches for assessment of damage probabilities.

An important problem is the comparison of damage probabilities obtained with these alternative methods. In this study, empirical and analytical approaches are compared in terms of damage data from a recent earthquake that occurred in Turkey. For this purpose, first, empirical damage probabilities are obtained from the damage database of the 17 August 1999 Kocaeli earthquake. Then, the results are compared with the damage rates from the analytical method. Results of this study and similar studies are important in terms of accurate estimation of seismic risks in earthquake-prone regions in the world.

Method

In this section, empirical and analytical methods for estimating damage state probabilities will be presented. Before that, damage probability matrices are explained briefly.

Damage Probability Matrices

Damage probability matrices (DPMs) were first introduced by Whitman (1973) for multistory buildings in the aftermath of the 1971 San Fernando earthquake. An element in this matrix, Pr(DS,I), gives the probability of occurrence of a damage state (DS) under an earthquake intensity, I. The sum of any column in this matrix is equal to unity. Table 1 shows an example damage probability matrix.

Damage state is the verbal or quantitative representation of the damage that would result in a structure under an earthquake of specific intensity. Verbal definitions are generally used in qualitative assessment of damage. A quantitative expression is used to represent the damage if the original cost of the structure is known. The ratio of the cost of repair to the cost of replacement of the structure is defined as damage ratio (DR). As the name implies, this ratio takes values that range from 0 % to 100 %. However, representative damage ratios are required in order to associate with the damage states and make the calculations easier. Therefore, the term central damage ratio (CDR) is defined for a representative value of each damage ratio. The CDR values in Table 1 are taken from Gürpınar et al. (1978).

Using a single damage ratio is preferred to summarize a full DPM. This ratio is called

Estimation of Potential Seismic Damage in Urban Areas, Fig. 1 Observed intensity map of the 17 August 1999 Kocaeli (Mw = 7.4) earthquake (Adapted from Özmen 1999)

mean damage ratio (MDR) and is obtained by the following equation:

$$MDR(I) = \sum_{DS} Pr(DS, I) * CDR(DS) \quad (1)$$

where $MDR(I)$ is the mean damage ratio corresponding to the intensity level I , $Pr(DS, I)$ is the damage state probability of the building type of interest subjected to the earthquake of intensity I , and $CDR(DS)$ is the central damage ratio corresponding to damage state DS .

In most of the previous studies, Modified Mercalli Intensity (MMI) is used as the seismic intensity scale in DPMs. Similarly, in this study MMI scale is employed to quantify the intensity of the ground shaking.

Empirical Method for Damage Probability Matrices

In the empirical approach, damage state probabilities are obtained with simple frequency analyses of different damage states in the damage database of interest. In other words, the damage

state probabilities given in Table 1 are calculated as follows:

$$Pr(DS, I) = \frac{N(DS, I)}{N(I)} \quad (2)$$

where $N(DS, I)$ is the number of buildings that are in damage state DS due to an earthquake with intensity I and $N(I)$ is the total number of buildings subjected to the same event.

In this study, regional empirical DPMs are formed using the detailed damage database of 17 August 1999 Kocaeli (Mw = 7.4) earthquake. This destructive earthquake caused significant structural damage resulting in almost 20,000 casualties and considerable economic losses. While computing empirical damage probabilities, initially the isoseismal (intensity) map of the earthquake is investigated (Fig. 1). Isoseismal maps demonstrate spatial distribution of seismic intensities in the form of contour lines of equal intensity values. These maps are mostly generated in the field in the aftermath of an earthquake. Based on the fact that different intensities are

Estimation of Potential Seismic Damage in Urban Areas, Table 2 Empirical damage probability matrix for Kocaeli city center (MMI = IX)

Damage state	CDR (%)	Masonry buildings	Reinforced concrete buildings
No damage	0	0.70	0.16
Light damage	5	0.12	0.30
Moderate damage	30	0.08	0.29

MDR (%)		11.91	31.75
Total number of flats		14.086	25.351

observed in different locations during the same event (Fig. 1), in this study city-based empirical DPMs are constructed.

While constructing the city-wise DPMs, damage assessment forms filled by the experts of the (former) General Directorate of Disaster Affairs of Turkey are used. The probability values per each damage state are calculated simply by Eq. 2. The resulting DPMs are based on assessment of households instead of buildings, since the data is collected on household basis. Converting number of households to the number of buildings is not performed since such a conversion would further introduce error into the data. The regional DPMs in this study are formed by processing the database involving approximately 170,000 flats in the central districts of Kocaeli, Sakarya, and Bolu. The DPMs are prepared in terms of two main types of buildings in Turkey: reinforced concrete and masonry buildings. Tables 2, 3, and 4 present the empirical DPMs constructed for city centers of Kocaeli, Sakarya, and Bolu, respectively, corresponding to the discrete MMI value experienced in each city. These city centers are all located in Northwestern Turkey, and they experienced significant damage in the 17 August Kocaeli earthquake.

As observed from Tables 2, 3, and 4, in Sakarya, the MDR for reinforced concrete buildings is found to be greater than those in Kocaeli and Bolu. On the other hand, the highest MDR for masonry buildings is observed in Kocaeli. The

Estimation of Potential Seismic Damage in Urban Areas, Table 3 Empirical damage probability matrix for Sakarya city center (MMI = X)

Damage state	CDR (%)	Masonry buildings	Reinforced concrete buildings
No damage	0	0.80	0.12

Moderate damage	30	0.04	0.25
Severe damage and collapse	85	0.07	0.41
MDR (%)		7.51	43.28
Total number of flats		78.444	22.463

Estimation of Potential Seismic Damage in Urban Areas, Table 4 Empirical damage probability matrix for Bolu city center (MMI = VII)

Damage state	CDR (%)	Masonry buildings	Reinforced concrete buildings
No damage	0	0.86	0.20
Light damage	5	0.06	0.16
Moderate damage	30	0.03	0.36
Severe damage and collapse	85	0.05	0.27
MDR (%)		5.50	34.64
Total number of flats		12.661	7.814

latter observation is expected since Kocaeli is the closest city center to the epicenter of the earthquake. It is however interesting to observe that the highest MDR for reinforced concrete buildings is the highest in Sakarya. This result can be explained as follows: It is well known that the local soil conditions in Sakarya are worse than those in Kocaeli, and several sites in Sakarya city center indeed experienced liquefaction during the earthquake. Thus, the soil amplifications at frequencies close to the fundamental modes of reinforced concrete buildings are most probably the cause of significant damage in those buildings in Sakarya.

These empirical results are compared with the analytical ones in section “[Comparison of Results from Alternative Methods.](#)”

Estimation of Potential Seismic Damage in Urban Areas, Fig. 2 Fragility curves of mid-rise reinforced concrete buildings (Erberik 2008b)

Analytical Method for Damage Probability Matrices

The first step of the analytical method involves construction of fragility curves based on the structural analyses of the building group of interest. Then, the continuous information on fragility curves is converted to discrete damage state probabilities in DPMs. There are different analysis approaches for deriving fragility curves: Static methods are simpler but yield only approximate results. Dynamic analyses are mostly more complex but they generate more accurate results in terms of structural response. In addition, nonlinear analyses should also be used in fragility analyses due to the fact that damage is directly related to nonlinear behavior. Currently, two common analytical methods for generating fragility curves are the nonlinear pushover method and nonlinear dynamic methods. In addition, it is possible to perform analyses on idealized models of buildings as single- or multi-degree-of-freedom structures.

In this study, in order to compare the empirical and analytical DPMs, previously available fragility curves for masonry and reinforced concrete buildings are used (Erberik 2008a, b). These curves are derived using the analytical method described previously, and they present the local characteristics of existing reinforced concrete and masonry buildings in Turkey. They are also validated against real data from

past major earthquakes. The reinforced concrete buildings are classified as “low rise” (1–3 stories) and “mid rise” (4–9 stories). These buildings are also classified with respect to their compliance to current seismic codes and their performance levels as “high,” “moderate,” and “low.” Thus, there are six subclasses for the buildings. Typical fragility curves for the reinforced concrete buildings are shown in Fig. 2. The MR abbreviation in the figure indicates “mid-rise” buildings while the letters A, B, and C represent the high, moderate, and low seismic performance levels. The masonry buildings, on the other hand, are classified as “urban engineered,” “urban non-engineered,” and “rural.” The corresponding abbreviations, respectively, are “UE,” “UN,” and “RN.” In addition to these, number of stories is another structural parameter used in the classification of masonry buildings. Figure 3 displays an example fragility curve for two-story urban-engineered and urban-non-engineered masonry buildings (UE2, UN2). For harmonization purposes, two limit states are selected: Lower limit state (LS1) is between no damage and moderate damage states, while the upper limit state (LS2) is between moderate damage and heavy damage/collapse states.

The information on fragility curves can be easily converted to DPMs. In the example shown in Fig. 4, the fragility curves indicate the exceedance probability of two different limit states (LS1, LS2) in terms of a selected ground

motion intensity parameter (peak ground acceleration, PGA in this case). The regions surrounding the fragility curves correspond to three different damage states (DS1, DS2, and DS3). To obtain the discrete probability of a damage state given an intensity level (PGA = 0.6 g in this case), a vertical line is drawn which intersects the fragility curves as shown in Fig. 4. This vertical line yields the probability of the building type of interest to experience different damage states under the corresponding PGA. In the example shown in Fig. 4, when PGA = 0.6 g, the probability of no damage (or light damage) is 7 %, the probability of moderate damage is 57 %, and the probability of severe damage (or collapse) is 36 %. This information constitutes one column of the DPM. If the same

procedure is repeated for other intensity levels, it is possible to form a full DPM.

Comparison of Results from Alternative Methods

As discussed previously, it is possible to obtain damage state probabilities with alternative approaches. In this study, in order to make a comparison with the empirical results, the analytical fragility curves complying with the characteristics of the existing building stock in Kocaeli, Sakarya, and Bolu are employed. Considering the local and structural-deficient characteristics of buildings in these city centers, fragility curves for “non-engineered” buildings are used.

Estimation of Potential Seismic Damage in Urban Areas, Table 5 Comparison of damage probabilities for masonry buildings in Kocaeli (MMI = IX)

Damage state	CDR (%)	Analytical approach	Empirical approach
No damage + light damage	2.5	0.90	0.81

Moderate damage	30	0.58	0.25
Severe damage + collapse	85	0.39	0.41
MDR (%)		50.8	43.2

The fragility curves given in Erberik (2008a, b) express the earthquake intensity in terms of PGA and peak ground velocity (PGV) for masonry and reinforced concrete buildings, respectively (Figs. 2 and 3). In order to make a comparison with the empirical damage state probabilities in Kocaeli, Sakarya, and Bolu, the PGA and PGV values recorded during the 17 August 1999 earthquake are used in the fragility curves. An important point here is the fact that there are different damage states in the analytical and empirical assessments: Thus, for a consistent comparison, the “none” and “light” damage states in the empirical DPMs are combined. Tables 5, 6, 7, 8, 9, and 10, respectively, present the comparison of two approaches in Kocaeli, Sakarya, and Bolu for masonry and reinforced concrete buildings.

According to the comparisons, the empirical and analytical DPMs yield similar results for masonry buildings in all city centers. However, the same observation is not valid for reinforced

concrete buildings: The discrete values of empirical and analytical damage state probabilities seem different. However, the MDR values are found to be consistent with each other for all building types at all locations.

The difference between empirical and analytical methods is indeed not surprising. Both methods involve inherent uncertainties: In the empirical approach, the values are directly dependent on the accuracy of the data collected in the field. Damage data collection in the aftermath of a large earthquake should be handled with care otherwise subjectivities arise in the resulting damage state probabilities. An example is conducting street surveys only in regions of severe damage while neglecting the areas with relatively “light” or “no damage” buildings, which would bias the resulting damage state probabilities.

In the analytical method, on the other hand, the accuracy of the results mostly relies on the

Estimation of Potential Seismic Damage in Urban Areas, Table 9 Comparison of damage probabilities for masonry buildings in Bolu (MMI = VII)

Damage state	CDR (%)	Analytical approach	Empirical approach
No damage + light damage	2.5	0.91	0.92
Moderate damage	30	0.06	0.03
Severe damage + collapse	85	0.02	0.05
MDR (%)		6.15	7.45

Estimation of Potential Seismic Damage in Urban Areas, Table 10 Comparison of damage probabilities for reinforced concrete buildings in Bolu (MMI = VII)

Damage state	CDR (%)	Analytical approach	Empirical approach
No damage + light damage	2.5	0.46	0.36
Moderate damage	30	0.53	0.36
Severe damage + collapse	85	0.01	0.27
MDR (%)		17.9	34.65

structural analysis approach taken or the idealizations of the exact buildings. For instance, the fragility curves for masonry buildings employed in this study are derived using three-dimensional building models; however, the curves for reinforced concrete buildings are based on equivalent single-degree-of-freedom models. Due to the equivalent idealized models, the analyses are simplified but on the other hand some accuracy is lost. This point is believed to be the main cause of difference between empirical and analytical results for the reinforced concrete buildings. This trade-off between cost of computing and cost of modeling real buildings more accurately is always a choice that a researcher must make.

Summary

In this study, observed damage state probabilities of masonry and reinforced concrete buildings in Turkey are compared with the damage state

probabilities obtained from analytical fragility curves. The damage data is collected in three city centers, which are all located in the most active seismic zone of Turkey, after the 17 August 1999 Kocaeli earthquake.

As a result of the comparisons in these city centers, in some cases very close results are obtained despite some noticeable differences in other cases. In particular, the use of equivalent simplified models of reinforced concrete buildings resulted in deviations from the empirical results. Such differences are expected as both approaches involve inherent uncertainties due to assumptions and simplifications made. However, in all cases, for all building types, the MDR values are found to be in the same order of magnitude. This observation is encouraging to use both approaches in the future.

According to the results of this case study, it is suggested that alternative methods are employed for estimating potential seismic damage in urban regions. Hybrid damage models are also recommended as they yield more accurate results. In the long run, results of this study and similar studies can be used in seismic loss estimation models, disaster management, emergency planning, as well as rapid response purposes in urban regions.

European Structural Design Codes: Seismic Actions

Michael N. Fardis

Department of Civil Engineering, School of Engineering, University of Patras, Patras, Greece

Synonyms

Design response spectra; Design seismic actions; Eurocode for seismic design, Seismic actions, Seismic response spectra

Introduction

Between 1992 and 1998, close to 60 Eurocodes were published by the European Committee for Standardization (CEN) as European pre-standards for structural design (ENVs). Their conversion to the first generation of European Standards (EN) for structural design started at the end of the 1990s and was concluded after the mid-2000s. The conversion entailed a thorough revision of the ENVs on the basis of recent scientific/technical developments and of comments from National Standards Bodies which are members of CEN.

Among the ten EN-Eurocodes, two cover the basis of structural design and the loadings (“actions”), one deals with geotechnical and foundation design, while five cover aspects specific to concrete, steel, composite (steel-concrete), timber, masonry, or aluminum construction. Instead of distributing the seismic design aspects to the EN-Eurocodes on

European Structural Design Codes: Seismic Actions, Table 1 Eurocode 8 parts

Part	EN	Title
1	EN 1998-1:2004	Design of structures for earthquake resistance – general rules, seismic actions, rules for buildings
2	EN 1998-2:2005	Design of structures for earthquake resistance – bridges
3	EN 1998-3:2005	Design of structures for earthquake resistance – assessment and retrofitting of buildings
4	EN 1998-4:2006	Design of structures for earthquake resistance – silos, tanks, pipelines
5	EN 1998-5:2004	Design of structures for earthquake resistance – foundations, retaining structures, geotechnical aspects
6	EN 1998-6:2005	Design of structures for earthquake resistance – towers, masts, chimneys

loadings, materials, or geotechnical design, all aspects of seismic design are covered by EN-Eurocode 8: “EN1998: Design of Structures for Earthquake Resistance.” This is for the convenience of countries with very low seismicity, as it gives them the option not to apply EN-Eurocode 8 at all.

EN-Eurocode 8 has six Parts, listed in Table 1.

The EN-Eurocodes are the recommended European structural design codes for civil engineering works and their parts (including prefabricated structural components), in order to facilitate the integration of the construction market in the European Union. The European Commission has published a “Recommendation on the implementation and use of Eurocodes for construction works and structural construction products” (European Commission 2003), according to which Member States should adopt the Eurocodes as a suitable tool for the structural design of construction works and refer to them in their national provisions on structural construction products. More specifically, the Eurocodes should be used as the basis for the technical specifications in the contracts for works and related engineering services in the public sector, as well as in the water, energy, transport, or telecommunications sectors.

According to (European Commission 2003), it is up to a Member State to select the level of safety and protection – which, according to (European Commission 2001), may include serviceability and durability – offered by civil engineering works on its national territory. To allow Member States to exercise this authority and accommodate geographical, climatic, and geological (including seismotectonic) differences without sacrificing harmonization of structural design codes at the European level, the notion of “Nationally Determined Parameters” (NDPs) has been adopted as the means to provide the necessary flexibility in the application of Eurocodes across (and outside) Europe. According to this approach, the EN-Eurocodes allow national choice of all key parameters or aspects that control the safety, durability, serviceability, and economy of civil engineering works designed and constructed to the EN-Eurocodes. The “Nationally Determined Parameters” in EN-Eurocodes include:

- Symbols (e.g., safety factors, the mean return period of the design seismic action, etc.)
- Technical classes (e.g., ductility classes)
- Procedures or methods (e.g., alternative models of calculation)

Alternative classes and procedures/methods considered as NDPs are identified and fully described in the normative text of the EN-Eurocode. For NDP-symbols, the EN-Eurocode may give a range of acceptable values and normally recommends in a nonnormative note a value for the symbol. It normally also recommends a class or a procedure/method among the alternatives identified and described in the EN-Eurocode text as NDPs (European Commission 2001).

Each Member State publishes its chosen values for the NDPs in a National Annex which accompanies the national version of the EN-Eurocode. According to European Commission (2003), Member States should adopt for the NDPs the choices recommended in the notes of the EN-Eurocode, in order to achieve the maximum feasible harmonization across the

EU. Member States should not diverge from the recommended choice, unless geographical, climatic, and geological differences or different levels of protection make it necessary. A National Annex may also contain country-specific data that are also considered by the EN-Eurocode as NDPs (e.g., a seismic zoning map, spectral shapes for the various types of soil profiles provided in Eurocode 8, etc.). A decision to adopt nationally or not an informative Annex of the EN-Eurocode is also stated there.

If the National Annex does not exercise national choice for some NDPs, the choice will be the responsibility of the designer, taking into account the conditions of the project and other national provisions (European Commission 2001).

A National Annex may provide supplementary information, noncontradictory to any of the rules of the EN-Eurocode. This may include references to other national documents, to assist the user in the application of the EN (European Commission 2001). What a National Annex cannot do is modify any EN-Eurocode provisions or replace them with other – e.g., national – rules. Although not encouraged, such deviations from the EN-Eurocode are allowed in national regulations other than the National Annex. However, when use is made of national regulations allowing deviation from certain Eurocode rules, the design will not be called “design according to EN-Eurocodes,” as by definition this term means compliance with all EN-Eurocode provisions, including the national choices for the NDPs (European Commission 2001).

If an EN-Eurocode is not considered relevant to a particular Member State, then a National Annex is not required. This may be the case for EN-Eurocode 8 in countries of very low seismicity (European Commission 2001).

CEN Member States have been given few years after the publication of an EN-Eurocode by CEN in English, French, and German to publish the corresponding National Annex (including the national choice for the NDPs). During that period, Member States have calibrated the NDPs so that, for the target safety level, structures designed according to the National version of the EN-Eurocodes will not cost significantly more

than those designed according to current National Standards (European Commission 2001).

CEN Member States have withdrawn those National Standards which conflict in some way with any EN-Eurocode, so that the EN-Eurocodes become the exclusive structural design standards in the European Union.

The revision of the EN-Eurocodes toward their second generation is expected to be complete by 2020, after starting in 2014.

Performance Requirements in EN-Eurocode 8 and Corresponding Seismic Hazard Levels

Seismic Design of New Buildings

Part 1 of EN-Eurocode 8 (CEN 2004a) provides for two-tier seismic design of new buildings, with the following explicit performance objective (Fardis et al. 2005):

- Under a rare seismic action: to protect life, by preventing collapse of the structure or its parts and by maintaining structural integrity and residual load capacity
- Under a frequent event: to reduce property loss by limiting structural and nonstructural damage or – for certain types of structures, such as tanks, pipelines or chimneys – to ensure integrity or a minimum operating level

The no-(local)-collapse performance level is achieved by dimensioning and detailing structural elements for a combination of strength and ductility that provides a safety factor between 1.5 and 2 against substantial loss of gravity load capacity and lateral load resistance. The damage limitation performance level is achieved by limiting the local or global deformations (normally the lateral displacements) of the building to levels acceptable for the integrity of all its parts (including nonstructural ones).

Although not explicitly stated, an additional performance objective in the design for ductility and energy dissipation is to prevent global collapse due to an extremely strong earthquake, like the “Maximum Considered Earthquake” (MCE)

of the US codes. Nonetheless, collapse may be imminent after such an earthquake (e.g., due to strong aftershocks) and repair may be unfeasible or economically prohibitive. Tolerance to extremely strong seismic actions is pursued through systematic and across-the-board application of the capacity design concept, which allows control of the inelastic response mechanism.

The two explicit performance levels – (local-) collapse prevention and damage limitation – are pursued under two different seismic actions. The seismic action under which (local-)collapse should be prevented is termed “design seismic action.” Given that issues of safety and economy are within the competence of individual Member States, the hazard levels for the seismic actions associated with these two performance levels – (local-)collapse prevention and damage limitation – are left open for national determination as NDPs. For buildings of ordinary importance, the recommendation in Part 1 of EN-Eurocode 8 is:

- A “design seismic action” (for local-collapse prevention), with recommended 10 % probability of been exceeded in 50 years (recommended mean return period: 475 years)
- A seismic action for damage limitation, with recommended 10 % probability of been exceeded (recommended mean return period: 95 years).

Seismic Assessment and Retrofitting of Existing Buildings

Part 3 of EN-Eurocode 8 (CEN 2005a) adopts a fully performance-based approach for the assessment and retrofitting of existing buildings (Fardis 2009). It defines three performance levels (called therein “limit states”):

- “Near collapse” (NC), which is similar to “collapse prevention” in the USA: The structure is heavily damaged, may have large permanent drifts, and retains little residual lateral strength or stiffness, but vertical elements can still carry the gravity loads. In the verifications, members may approach their ultimate force or deformation capacity.

- “Significant damage” (SD), corresponding to “life safety” in the USA and to the (local-) collapse prevention performance level to which new buildings are designed according to Part 1 of EN-Eurocode 8 (CEN 2004a). The structure is significantly damaged, may have moderate permanent drifts, but retains some residual lateral strength and stiffness and its full vertical load-bearing capacity. Repair may be uneconomic. The verifications should provide a margin against member ultimate capacities.
- “Damage limitation” (DL), corresponding to “immediate occupancy” in the USA. The structure has no permanent drifts; its elements have no permanent deformations, retain fully their strength and stiffness and do not need repair. Members should be verified to remain elastic.

The “seismic hazard” levels for which the three limit states are required are meant to be decided nationally as NDPs, or by the owner, if not fixed in the National Annex. Part 3 of EN-Eurocode 8 itself gives no recommendation, but mentions that the performance objective suitable to ordinary new buildings is a 225-year earthquake (20 % probability of been exceeded in 50 years), a 475-year event (10 % probability in 50 years), or a 2,475-year one (2 % in 50 years), for the DL, the SD, or the NC “limit state,” respectively. National Authorities also decide whether all three limit states need to be verified or whether checking one or two limit states at the corresponding seismic hazard level suffices. Part 3 of EN-Eurocode 8 guides National Authorities to choose the set of limit states to be checked, as well as the return period of the corresponding seismic actions, depending on whether assessment and retrofitting takes place as part of an “active” program (in which owners of certain categories of buildings are required to meet specific deadlines for completion of the assessment and – depending on its outcome – of the retrofitting) or a “passive” one (that associates seismic assessment – possibly leading to retrofitting – with discontinued use of the building). In “active” programs the relevant requirements may be less stringent than in

“passive” ones, while in “passive” programs triggered by remodelling the building, performance requirements for the assessment and the retrofitting may graduate with the extent and cost of the remodelling work undertaken. With this guidance, National Authorities will hopefully set the performance requirements for existing buildings so that, in the long run, the percentage of the existing building stock to be retrofitted is optimal for the society and the national economy as a whole.

Seismic Design of New Bridges

Part 2 of EN-Eurocode 8 (CEN 2005b) requires single-tier seismic design of new bridges with the following explicit performance objective:

- The bridge must retain its structural integrity and have sufficient residual resistance to be used for emergency traffic without any repair after a rare seismic event: the “design seismic action”; any damage due to this event must be easily repairable.

Although called “non-collapse requirement,” in reality this corresponds to life safety, rather than to near collapse, because sufficient residual resistance has to be available after the design seismic event for immediate use by emergency traffic (Kolias et al. 2012).

Part 2 of EN-Eurocode 8 (CEN 2005b) calls also for limitation of damage under a loosely defined seismic action with high probability of been exceeded in the bridge’s lifetime; such damage must be minor and limited only to secondary components and to the parts of the bridge intended for controlled damage under the “design seismic action.” However, this requirement is of no practical consequence for design: it is presumed to be implicitly met, if all the criteria for compliance with the “non-collapse requirement” are checked and met under the “design seismic action” (Kolias et al. 2012). This should be contrasted with new buildings, for which Part 1 of EN-Eurocode 8 (CEN 2004a) provides explicit checks under a well-defined “damage limitation” seismic action. However, the damage checks (inter-story drifts)

normally refer to nonstructural elements, which are not present in bridges.

Elastic Response Spectra

Introduction: Elastic Spectra

The seismic action is considered to impart concurrent translational motion in three orthogonal directions: the vertical, and two horizontal ones, at right angles to each other. The motion is taken to be applied at the interface between the structure and the ground.

The most common representation of the seismic action in structural design codes is via the response spectrum of an elastic Single-Degree-of-Freedom (SDOF) oscillator with 5 % viscous damping ratio. It gives the maximum response of this oscillator to the ground motion, as a function of its natural period T (hence the term “spectrum”). Any other alternative representation of the seismic action (e.g., in the form of acceleration time-histories) should conform to the 5 %-damped elastic response spectrum. This is indeed the representation chosen in EN-Eurocode 8 (CEN 2004a, b, 2005a, b, c, 2006).

Because:

- earthquake ground motions are traditionally recorded as acceleration time-histories.
- seismic design is still based on forces, conveniently derived from accelerations;

the pseudo-acceleration response spectrum, $S_a(T)$, is normally used. If spectral displacements, $S_d(T)$, are of interest (notably, for displacement-based design, assessment or retrofitting), they can be obtained from $S_a(T)$ assuming simple harmonic oscillation:

$$S_d(T) = (T/2\pi)^2 S_a(T) \quad (1)$$

Spectral pseudo-velocities can also be obtained from $S_a(T)$ as:

$$S_v(T) = (T/2\pi) S_a(T) \quad (2)$$

Pseudo-values do not correspond to the real peak spectral velocity or acceleration. For

damping ratio up to 10 % and for natural period T between 0.2 and 1.0 s, the pseudo-velocity spectrum approximates well the actual relative velocity spectrum.

The EN-Eurocode 8 spectra include ranges of:

- Constant spectral pseudo-acceleration for natural periods between two periods denoted by T_B and T_C
- Constant spectral pseudo-velocity between periods T_C and T_D
- Constant spectral displacement for periods longer than T_D

Design Ground Acceleration: Importance Classes

In EN-Eurocode 8, the elastic response spectrum is taken as proportional (“anchored”) to the peak acceleration of the ground, namely, to:

- The horizontal peak acceleration, a_g , for the horizontal component(s) of the seismic action or
- The vertical peak acceleration, a_{vg} , for the vertical component

Data from Europe available at the time Eurocode 8 was drafted could not support the dependence of the elastic spectrum on additional parameters. According to (Bommer and Scott 2000) and (Rey et al. 2002), the shape of elastic response spectra of European records does not show a clear dependence on distance – epicentral or to the fault.

The basis of the seismic design of new structures in EN-Eurocode 8 is the “design seismic action,” for which the no-(local-)collapse requirement should be met. The “design seismic action” is specified through the “design ground acceleration” in the horizontal direction, a_g , which is equal to the “reference peak ground acceleration” on rock from national zonation maps, times the importance factor, γ_I , of the structure:

$$a_g = \gamma_I a_{gR} \quad (3)$$

(see below; for structures of ordinary importance, $\gamma_I = 1.0$).

Within a single-tier design framework, enhanced safety of facilities that are essential or have large occupancy is normally achieved by modifying the hazard level (the mean return period) of the “design seismic action.” To this end, the seismic action is multiplied by an “importance factor,” γ_I .

By definition, $\gamma_I = 1.0$ for structures of ordinary importance (called “Importance Class II” in Parts 1, 2 and 3 of EN-Eurocode 8 (CEN 2004a, 2005a, b)).

Concerning buildings, Part 1 of EN-Eurocode 8 (CEN 2004a) recommends a value $\gamma_I = 1.2$ for those whose collapse may have unusually large social or economic consequences (large occupancy buildings, such as schools or public assembly halls) or those housing institutions of cultural importance, such as museums (buildings of “Importance Class III” in EN-Eurocode 8); $\gamma_I = 1.4$ is recommended for buildings which are essential for civil protection during the immediate post-earthquake period, categorized as “Importance Class IV” (hospitals, fire or police stations, power plants, etc.); for buildings of minor importance for public safety (i.e., belonging to “Importance Class I,” comprising agricultural and similar buildings), Part 1 of EN-Eurocode 8 recommends a value $\gamma_I = 0.8$.

Concerning bridges, Part 2 of EN-Eurocode 8 (CEN 2005b) recommends classifying under “Importance Class III” the ones which are crucial for communications especially in the immediate post-earthquake period (including access to emergency facilities), or whose downtime may have a major economic or social impact, or which, by failing, may cause large loss of life, as well as major bridges with a target design life longer than the ordinary nominal life of 50 years. For this importance class, it recommends taking $\gamma_I = 1.3$. Bridges which are not critical for communications, or considered not economically justified to design for the standard bridge design life of 50 years, should be classified under “Importance Class I” with a recommended value $\gamma_I = 0.85$, according to Part 2 of EN-Eurocode 8.

The importance classification of towers, masts, and chimneys (CEN 2005c) is similar to that of buildings: of reduced importance for

public safety, of ordinary importance, of higher importance for public safety in terms of potential casualties, or vital for civil protection; the recommended values of the NDP-importance factor γ_I are the same as for buildings.

The important classification of tanks, pipelines, or silos (CEN 2006) is more complex, taking into account not only risk to life but also the economic and social consequences of damage or failure, as well as system and redundancy aspects. The recommended values of the NDP-importance factor γ_I are equal to 0.8, 1.0, 1.2, or 1.6, if the risk to life and the economic or social consequences of failure are low, medium, high, or exceptional, respectively.

The “reference peak ground acceleration” corresponds to the reference return period, T_{NCR} , of the “design seismic action” for structures of ordinary importance (“Importance Class II”). It is reminded that under the Poisson assumption of earthquake occurrence (i.e., that the number of earthquakes in an interval of time depends only on the length of the interval in a time-invariant way), the return period, T_R , of seismic events exceeding a certain threshold is related to the probability, P , that the threshold will be exceeded in T_L years as

$$T_R = -T_L / \ln(1 - P) \quad (4)$$

So, for a given T_L (e.g., for the reference design life of $T_{LR} = 50$ years), the seismic action may equivalently be specified either via its mean return period, T_R , or its probability of been exceeded in T_L years, P_R . Values of the importance factor greater or lower than 1.0 correspond to mean return periods longer or shorter, respectively, than T_{NCR} . It is in the authority of the country to select the value of T_{NCR} that gives the appropriate trade-off between economy and public safety in its territory, as well as the importance factors for building other than ordinary, taking into account the specific regional features of the seismic hazard. Part 1 of EN-Eurocode 8 (CEN 2004a) recommends the value $T_{NCR} = 475$ years.

The mean return period, $T_R(a_g)$, of a peak ground acceleration exceeding a value a_g is the

inverse of the annual rate, $\lambda_a(a_g)$, at which this acceleration level is exceeded:

$$T_R(a_g) = 1/\lambda_a(a_g) \quad (5)$$

A functional form commonly used for $\lambda_a(a_g)$ is

$$\lambda_a(a_g) = K_o(a_g)^{-k} \quad (6)$$

If the exponent k (: slope of the “hazard curve” $\lambda_a(a_g)$ in a log-log plot) is about constant, two peak ground acceleration levels a_{g1} , a_{g2} , corresponding to two different mean return periods, $T_R(a_{g1})$, $T_R(a_{g2})$, are related as

$$\frac{a_{g1}}{a_{g2}} = \left(\frac{T_R(a_{g1})}{T_R(a_{g2})} \right)^{1/k} \quad (7)$$

The value of k characterizes the seismicity of the site. In regions where the difference in peak ground acceleration of frequent and very rare seismic excitations is very large, k is low (around 2); in such regions, full performance-based design or assessment at several performance levels with widely different hazard levels is very meaningful. Large values of k (above 4) are typical of regions where high ground acceleration levels are almost as frequent as smaller ones; one performance level (normally the one associated with the lowest among the hazard levels) will almost always govern there; performance-based design or assessment at the other levels may be redundant.

The value of the importance factor γ_I may be determined as follows: let's suppose that, for “Importance Class II” (ordinary), the “reference peak ground acceleration” on rock, a_{gR} , has a probability, P_{LR} , of been exceeded in the reference design life of $T_{LR} = 50$ years; then, the “design ground acceleration,” a_g , which has that probability, P_{LR} , of been exceeded in T_L years is obtained by multiplying a_{gR} by

$$\gamma_I = (T_L/T_{LR})^{1/k} \quad (8a)$$

Alternatively, to have a probability of exceeding the “design ground acceleration,” P_L , in T_{LR}

years, which is different from the reference probability, P_{LR} , in the same T_{LR} years, a_{gR} should be multiplied by

$$\gamma_I = (P_{LR}/P_L)^{1/k} \quad (8b)$$

Ground Acceleration of Seismic Actions Other Than the “Design Seismic Action”

Design for damage limitation under the corresponding seismic action is explicitly required for buildings (as well as for tanks, pipelines, and chimneys, but not for bridges). The ratio, v , of the PGA of the seismic action for damage limitation to the “design seismic action” (for local-collapse prevention) reflects the difference in hazard levels. It is an NDP, with recommended values for buildings, silos, tanks, and pipelines equal to 0.5 for Importance Classes I and II or 0.4 for III and IV. This gives a ground acceleration, $(v\gamma_I)a_{gR}$, equal to 40 %, 50 %, 48 %, and 56 % of a_{gR} , for Importance Classes I, II, III, and IV, respectively; in other words, the property protection is about the same for ordinary, large occupancy, or essential facilities, although the protection they offer against collapse may be very different.

The approach highlighted at the end of the last section for the estimation of the importance factor, γ_I , on the basis of the Poisson assumption of earthquake occurrence may be modified to determine the ratio, v , of the ground acceleration of the damage limitation seismic action, va_g , to the “design ground acceleration,” a_g . If the seismic action for damage limitation has a probability of been exceeded in T_{DL} years which is the same as that of exceeding the “design seismic action” in a design life of T_L years, then a_g should be multiplied by

$$v = (T_{DL}/T_L)^{1/k} \quad (9)$$

EN-Eurocode 8 recommends in a note a probability of 10 % for exceeding the damage limitation seismic action in $T_{DL} = 10$ years. For these recommended values, Eq. 4 gives a mean return period of 95 years. The value of v should vary with the exponent k ; in order for the recommended values of v for buildings (equal to

0.4 or 0.5) to be consistent with the other recommended values, k should be around 2.

If the construction phase is long and in its duration the structural system is much more vulnerable to earthquakes than after completion (as, e.g., in segmental construction), the owner may specify seismic performance requirements during construction and the associated compliance criteria. Equation 4 may then be applied, using the estimated duration of construction, T_c , as T_L , to give the mean return period of the seismic action which has the target probability of been exceeded, P (e.g., $P = 0.05$). The resulting mean return period may be used as $T_R(a_{g1})$ in Eq. 7 to find the peak ground acceleration, a_{g1} , with probability P of been exceeded during construction. In that case, $a_{g2} = a_{gR}$ and $T_R(a_{g2}) = T_{NCR}$ (Kolias et al. 2012).

EN-Eurocode 8 adopts the same spectral shape for the different seismic actions to be used at different performance levels or purposes. The difference in the hazard level is reflected only through the peak ground acceleration to which the spectrum is anchored.

Elastic Response Spectra of the Horizontal Seismic Action Components in EN-Eurocode 8

The elastic response spectral acceleration, $S_a(T)$, due to a single horizontal component of the seismic action is described in EN-Eurocode 8 by the following expressions:

In the “short-period range”

$$0 \leq T \leq T_B : S_a(T) = a_g S \left[1 + \frac{T}{T_B} (2.5\eta - 1) \right] \quad (10a)$$

In the “constant spectral pseudo-acceleration range”:

$$T_B \leq T \leq T_C : S_a(T) = a_g S \cdot 2.5\eta \quad (10b)$$

In the “constant spectral pseudo-velocity range”:

$$T_C \leq T \leq T_D : S_a(T) = a_g S \cdot 2.5\eta \left[\frac{T_C}{T} \right] \quad (10c)$$

In the “constant spectral displacement range”:

European Structural Design Codes: Seismic Actions, Table 2 Values of viscous damping, ζ , for different structural materials

Material	Damping (%)
Reinforced concrete components	5
Prestressed concrete components	2
Welded steel components	2
Bolted steel components	4

$$T_D \leq T \leq 4 \text{ sec} : S_a(T) = a_g S \cdot 2.5\eta \left[\frac{T_C T_D}{T^2} \right] \quad (10d)$$

where

a_g is the design ground acceleration on rock, from Eq. 3

S is the “soil factor”

$$\eta = \sqrt{10/(5 + \zeta)} \geq 0.55 \quad (11)$$

is the correction factor per (Bommer and Elnashai 1999) for values of the viscous damping ratio, ζ , other than the reference value of 5 %. In fact, the value $\zeta = 5\%$ is considered as representative of cracked reinforced concrete structures. The values of ζ specified in Part 2 of Eurocode 8 (CEN 2005b) for components of various structural materials are listed in Table 2.

The terms “constant spectral pseudo-velocity range” and “constant spectral displacement range” used above in Eq. 10c and 10d, respectively, are a direct consequence of Eqs. 1 and 2, alongside the functional dependence of $S_a(T)$ on T in Eq. 10c and 10d.

By definition, $S = 1$ over rock (called “type A ground”). The value $a_g S$ plays the role of an “effective ground acceleration,” as the spectral acceleration at the constant spectral acceleration plateau is always equal to $2.5a_g S$. The “soil factor,” S , amplifies uniformly the entire spectrum by S over the spectrum for rock. This feature came out of the studies that provided the background for the Eurocode 8 spectra (Rey et al. 2002).

The values of the “corner” periods T_B , T_C , and T_D (i.e., the extent of the ranges of constant spectral pseudo-acceleration, pseudo-velocity, and displacement) and of the soil factor, S , are taken

European Structural Design Codes: Seismic Actions, Table 3 Ground types in EN-Eurocode 8 for the definition of the seismic action

	Description	$v_{s,30}$ (m/s)	N_{SPT}	c_u (kPa)
A	Rock outcrop, with less than 5 m of cover by weaker material	>800	–	–
B	Very dense sand or gravel, or very stiff clay, with depth of several tens of meters and mechanical properties gradually increasing with depth	360–800	>50	>250
C	Dense to medium-dense sand or gravel, or stiff clay, several tens to many hundreds meters deep	180–360	15–50	70–250
D	Loose-to-medium sand or gravel, or soft-to-firm clay	<180	<15	<70
E	Surface alluvium layer with $v_s < 360$ m/s and thickness from 5 to 20 m, underlain by rock (with $v_s > 800$ m/s)			
S_1	≥ 10 m thick soft clay or silt, with plasticity index >40 and high water content	<100	–	10–20
S_2	Liquefiable soils; sensitive clays or any soil not of type A to E or S_1			

to depend mainly on “ground type.” In the EN-Eurocodes, the term ground includes any type of soil, as well as rock. EN-Eurocode 8 recognizes five standard ground types, as well as two special ground types, S_1 , S_2 , for which there are no recommended values for T_B , T_C , T_D , or S . Note that in reality the value of S decreases with the intensity of the motion (as measured by a_g) owing to the increased nonlinearity of the soil, but this effect has been neglected in EN-Eurocode 8.

The five standard ground types, A, B, C, D, and E and the two special ones, S_1 and S_2 , per EN-Eurocode 8 are described in Table 3. The reference approach to characterize the ground in this table is through the average value of shear wave velocity, $v_{s,30}$, at the top 30 m:

$$v_{s,30} = \frac{30}{\sum_{i=1,N} \frac{h_i}{v_i}} \quad (12)$$

where h_i and v_i are, respectively, the thickness (in m) and the shear wave velocity at small shear strains (less than 10^{-6}) of the i -th layer in N layers. If the value of $v_{s,30}$ is not available, the Standard Penetration Test (SPT) blow-count number may be used for soil types B, C, or D, according to the correspondence of SPT to $v_{s,30}$ in (Ohta and Goto 1976). If neither the SPT number nor $v_{s,30}$ is available, the undrained cohesive resistance, c_u , may be used to characterize the soil.

Ground belonging to the two special types, S_1 and S_2 , deserves a special, site-specific study to

define the seismic action. For ground-type S_1 , the special study should take into account the thickness and the v_s -value of the soft clay or silt layer and the difference with the underlying materials and should quantify their effects on the elastic response spectrum. Note that soils of type S_1 may have low internal damping and exhibit linear behavior over a large range of strains, producing peculiar amplification of the bedrock motion and unusual or abnormal soil-structure interaction effects. The scope of the site-specific study should also address the possibility of soil failure under the design seismic action (especially at ground type S_2 deposits with liquefiable soils or sensitive clays).

The values of T_B , T_C , T_D , and S for the five standard ground types A to E are meant to be defined by each country in the National Annex to Eurocode 8, depending on the magnitude of earthquakes contributing the most to the hazard. The geological conditions at the site may also be taken into account, in addition to the properties of the top 30 m of ground, to determine these values.

Instead of spectral amplification factors that decrease – probably through the S factor – with increasing design acceleration (spectral or ground) because of the soil nonlinearity effect (as in the US codes), the non-binding recommendation in a note in Part 1 of EN-Eurocode 8 is to have two types of spectra:

- Type 1: for moderate to large magnitude earthquakes

European Structural Design Codes: Seismic Actions, Table 4 Recommended parameter values for the standard horizontal elastic response spectra in EN-Eurocode 8

Ground type	Spectrum type 1				Spectrum type 2			
	S	T_B (s)	T_C (s)	T_D (s)	S	T_B (s)	T_C (s)	T_D (s)
A	1.00	0.15	0.40	2.00	1.00	0.05	0.25	1.20
B	1.20	0.15	0.50	2.00	1.35	0.05	0.25	1.20
C	1.15	0.20	0.60	2.00	1.50	0.10	0.25	1.20
D	1.35	0.20	0.80	2.00	1.80	0.10	0.30	1.20
E	1.40	0.15	0.50	2.00	1.60	0.05	0.25	1.20

European Structural Design Codes: Seismic Actions, Fig. 1 Five percent-damped horizontal elastic response spectra of type 1 (*left*) and 2 (*right*) recommended in EC8

for the five standard ground types of Table 3 (PGA on rock equal to 1 g)

- Type 2: for low magnitude ones (e.g., with surface magnitude less than 5.5) at close distance, producing motions rich in high frequencies over soft soils

The values of T_B , T_C , T_D , and S recommended in a non-binding note in Part 1 of EN-Eurocode 8 for the five standard ground types A to E are given in Table 4, giving the shapes depicted in Fig. 1. These values are based on (Rey et al. 2002) and European strong motion data (Ambraseys et al. 2000). There are certain regions in Europe (e.g., where the hazard is contributed mainly by strong, intermediate-depth earthquakes, as in the part of the eastern Balkans affected by the Vrancea region) where the two recommended spectral shapes may not be suitable. The lower S -values of type 1 spectra are due to the larger soil nonlinearity in the stronger ground motions

produced by moderate to large magnitude earthquakes. The recommended values of the period T_D at the outset of the constant spectral displacement region seems rather low. For flexible structures (e.g., those with seismic isolation) they may not lead to safe-sided designs. A safeguard against the rapid decay of the elastic spectrum for $T > T_D$ is provided by the lower bound of $0.2a_g S$ recommended in Part 1 of EN-Eurocode 8 for the design spectral accelerations (see Eq. 13c, 13d in section “Design Spectrum for Force-Based Design With Linear Analysis per EN-Eurocode 8”).

Simplified Design Rules, or Exemption from Applying EN-Eurocode 8, for Low Design Ground Acceleration

EN-Eurocode 8 says that its provisions need not be applied in “cases of very low seismicity,”

leaving to the National Annex to decide which combination of categories of structures, ground types, and seismic zones in a country qualify as “cases of very low seismicity.” It recommends (in a note) as a criterion for the “cases of low seismicity,” either the value of the design ground acceleration on type A ground (i.e., on rock), a_g , per Eq. 3, or the corresponding value, $a_g S$, over the ground type of the site. The recommended threshold values for the very low seismicity cases are 0.04 g for a_g or 0.05 g for $a_g S$. As the value of a_g includes the importance factor γ_I , certain structures in a region may be exempted from the application of EN-Eurocode 8, while others (those housing essential or large occupancy facilities) may not be. This is consistent with the notion that the exemption from the application of Eurocode 8 is due to the inherent lateral force resistance of any structure designed for non-seismic loadings, neglecting any contribution from the ductility and energy dissipation capacity. As EN-Eurocode 8 considers that, thanks to its overstrength, any structure is entitled to a behavior factor, q , of at least 1.5, the value of 0.05 g for $a_g S$, recommended as the threshold for very low seismicity cases, implies an assumed inherent lateral force capacity of $0.05 \times 2.5/1.5 = 0.083$ g, which is a reasonable assumption. If a National Annex states that the entire national territory is considered as a “case of very low seismicity,” then EN-Eurocode 8 does not apply at all in the country.

In cases of “low seismicity,” EN-Eurocode 8 permits simplified seismic design procedures: e.g., to design a concrete, steel, composite (steel-concrete), or masonry building to EN-Eurocodes 2, 3, 4, or 6, respectively, alone, using very few rules from Part 1 of EN-Eurocode 8 (CEN 2004a); to design a bridge for “limited ductile” behavior, with simplified rules defined in Part 2 of EN-Eurocode 8 (CEN 2005b); etc. Again it leaves to the National Annex to decide which combination of categories of structures, ground types, and seismic zones in a country belongs to the “cases of low seismicity” and recommends (in a note) employing in the criterion either the

value of the design ground acceleration on type A ground (i.e., on rock), a_g , or the corresponding value, $a_g S$, over the ground type of the site. Moreover, it recommends a value of 0.08 g for a_g , or of 0.10 g for $a_g S$, as the threshold for the low seismicity cases.

Elastic Response Spectra of the Vertical Seismic Action Component in EN-Eurocode 8

EN-Eurocode 8 requires designers to take into account the vertical component of the seismic action in design only in certain very well-prescribed situations.

- In buildings, only if the design ground acceleration in the vertical direction, a_{vg} , exceeds 0.25 g and even then only in the following cases:
 - In base-isolated buildings or
 - For (nearly) horizontal members (beams, girders, or slabs) which:
 - Have a span of at least 20 m or
 - Cantilever over at least 5 m or
 - Support directly columns or
 - Are prestressed
- In bridges, for the seismic design of:
 - Prestressed concrete decks (with the vertical component acting upwards)
 - Any bearings
 - Any seismic links
 - Piers in zones of high seismicity:
 - If the pier is already taxed by bending due to permanent actions on the deck or
 - The bridge is less than 5 km from an active seismotectonic fault (defined as one where the average historic slip rate is at least 1 mm/year and there is topographic evidence of seismic activity in the past 11,000 years); in that case, site-specific spectra which account for near-source effects should be used.
- For silos
- For tanks

Therefore, the practical importance of the vertical spectrum is less than that of the horizontal.

Consistent with the findings of (Bozorgnia and Campbell 2004), the vertical elastic response spectrum is defined independently of the horizontal response spectra, as follows:

In the “short-period range”:

$$0 \leq T \leq T_B : S_{a, \text{vert}}(T) = a_{\text{vg}} \left[1 + \frac{T}{T_B} (3\eta - 1) \right] \quad (13a)$$

In the “constant spectral pseudo-acceleration range”:

$$T_B \leq T \leq T_C : S_{a, \text{vert}}(T) = a_{\text{vg}} \cdot 3\eta \quad (13b)$$

In the “constant spectral pseudo-velocity range”:

$$T_C \leq T \leq T_D : S_{a, \text{vert}}(T) = a_{\text{vg}} \cdot 3\eta \left[\frac{T_C}{T} \right] \quad (13c)$$

In the “constant spectral displacement range”:

$$T_D \leq T \leq 4s : S_{a, \text{vert}}(T) = a_{\text{vg}} \cdot 3\eta \left[\frac{T_C T_D}{T^2} \right] \quad (13d)$$

with η from Eq. 11.

The main differences between the horizontal and the vertical spectra are in:

- The amplification factor in the constant spectral pseudo-acceleration plateau, set equal to 3 instead of 2.5
- The lack of a uniform amplification of the entire spectrum due to the type of soil

Part 1 of EN-Eurocode 8 recommends in a note the following non-binding values of T_B , T_C , and T_D and of the design ground acceleration in the vertical direction, a_{vg} (see Fig. 2):

- $T_B = 0.05$ s.
- $T_C = 0.15$ s.
- $T_D = 1.0$ s.

European Structural Design Codes: Seismic Actions,
Fig. 2 Five percent-damped vertical elastic response spectrum recommended in EC8 for vertical PGA on rock $a_{\text{vg}} = 1$ g

- $a_{\text{vg}} = 0.9a_g$, if the type 1 spectrum applies to the site.
- $a_{\text{vg}} = 0.45a_g$, if the type 2 spectrum is used.

The vertical response spectrum recommended in Part 1 of EN-Eurocode 8 is based on work and data specific to Europe (Ambraseys and Simpson 1996; Elnashai and Papazoglou 1997).

The ratio a_{vg}/a_g is known to be higher at short distances (epicentral or to a causative fault). However, as distance does not enter as a parameter in the definition of the seismic action in EN-Eurocode 8, the type of spectrum has been chosen as the parameter determining this ratio, on the basis of the finding that a_{vg}/a_g increases also with magnitude (Ambraseys and Simpson 1996; Abrahamson and Litehiser 1989), which in turn determines the selection of the type of spectrum.

Design Spectrum for Force-Based Design with Linear Analysis per EN-Eurocode 8

Design Spectrum for the Horizontal Components

For the horizontal components of the seismic action, the design spectrum in Part 1 of

EN-Eurocode 8 for force-based design of new structures is:

In the “short-period range”:

$$0 \leq T \leq T_B : S_{a,d}(T) = a_g S \left[\frac{2}{3} + \frac{T}{T_B} \left(\frac{2.5}{q} - \frac{2}{3} \right) \right] \quad (14a)$$

In the “constant spectral pseudo-acceleration range,”

$$T_B \leq T \leq T_C : S_{a,d}(T) = a_g S \frac{2.5}{q} \quad (14b)$$

In the “constant spectral pseudo-velocity range,”

$$\begin{aligned} T_C \leq T \leq T_D : S_{a,d}(T) \\ = a_g S \frac{2.5}{q} \left[\frac{T_C}{T} \right], S_{a,d}(T) \geq \beta a_g \end{aligned} \quad (14c)$$

In the “constant spectral displacement range,”

$$\begin{aligned} T_D \leq T : S_{a,d}(T) \\ = a_g S \frac{2.5}{q} \left[\frac{T_C T_D}{T^2} \right], S_{a,d}(T) \geq \beta a_g \end{aligned} \quad (14d)$$

The value $2/3$ in Eq. 14a is the inverse of the overstrength factor of 1.5 considered in EN-Eurocode 8 to always be available, even without any design measures for ductility and energy dissipation. Factor β in Eq. 14c, 14d gives a lower bound for the horizontal design spectrum, acting as a safeguard against excessive reduction of the design forces due to the flexibility of the system (real or presumed in the design). Its recommended value in Part 1 of EN-Eurocode 8 is 0.2. Its practical implications may be particularly important, in view of the relatively low values recommended by Eurocode 8 for the corner period T_D at the outset of the constant spectral displacement range.

Design Spectrum in the Vertical Direction

The design spectrum in the vertical direction is obtained by substituting in Eqs. 14 the design ground acceleration in the vertical direction, a_{vg} , for the “effective ground acceleration” $a_g S$.

There is no clear, well-known energy dissipation mechanism for the response in the vertical direction. So, the “behavior factor” q in that direction is attributed to overstrength alone and is taken equal to 1.5, unless a higher value is supported by special studies and analyses.

Peak Ground Displacement and Displacement Response Spectrum

The value given in Part 1 of EN-Eurocode 8 for the design ground displacement, d_g , that corresponds to the design ground acceleration, a_g , is based on the assumption that the spectral displacement in the constant spectral displacement range (derived through Eq. 1 from the spectral acceleration at the beginning of that range at $T = T_D$, as given from Eq. 3 for the end of the constant pseudo-velocity range at $T = T_D$) is an amplification factor of 2.5 over the ground displacement that corresponds to the design ground acceleration, a_g . Taking $(T/2\pi)^2 \approx 40$, we obtain (for a_g in m/s^2 , not in g 's):

$$d_g = 0.025 a_g S T_C T_D \quad (15)$$

Equation 15 overestimates the ratio d_g/a_g , compared to more accurate predictions as a function of magnitude and distance based on (Ambraseys et al. 1996; Bommer and Elnashai 1999).

An Informative Annex in Part 1 of EN-Eurocode 8 gives also the displacement response spectrum, $S_d(T)$, including its long-period tail, beyond the upper end ($T = 4$ s) where Eq. 10d applies – alongside Eq. 1. More specifically (see Fig. 3):

- The applicability of Eq. 10d is extended beyond 4 s, up to a new control period $T_E > 4$ s.
- For $T < T_E$, $S_a(T)$, as given by Eqs. 10, may be converted to $S_d(T)$ through Eq. 1.
- Beyond T_E , $S_d(T)$ is taken to decrease linearly with T till a new control period T_F , where $S_d(T)$ becomes equal to d_g .

European Structural Design Codes: Seismic Actions,
Fig. 3 Shape of displacement response spectrum in
 EN-Eurocode 8

So, the tail of the displacement response spectrum is obtained as

$$T_E \leq T \leq T_F : S_d(T) = \left[2.5\eta + \left(\frac{T - T_E}{T_F - T_E} \right) (1 - 2.5\eta) \right] d_g \quad (16a)$$

$$T \geq T_F : S_d(T) = d_g \quad (16b)$$

with η from Eq. 11.

Values are given for the control periods, T_E and T_F , only for situations where the type 1 spectrum is considered to apply. Then, based on (Tolis and Faccioli 1999), T_E is taken as:

- $T_E = 4.5$ s for ground type A
- $T_E = 5.0$ s for ground type B
- $T_E = 6.0$ s for ground types C, D, or E

while T_F is always assumed equal to 10 s.

The above displacement response spectrum in EN-Eurocode 8 was supported by data from Europe (Bommer et al. 1998; Bommer and Elnashai 1999) at least up to periods of 3 s. However, as the European digital data from which the displacement response at longer periods can be reliably established were very limited at that time (Faccioli et al. 2004), they were supplemented with information from other regions of the world, for instance, from digital records from the 1995 Kobe earthquake, normally filtered at 20 s (Tolis and Faccioli 1999). This is one reason for not

giving values for T_E and T_F in situations where the type 2 spectrum is considered appropriate.

Topographic and Near-Source Effects on the Seismic Action

EN-Eurocode 8 provides for topographic amplification (ridge effect, etc.) of the seismic action for all types of structures. Such effects have been indeed identified in past earthquakes in Italy (Faccioli et al. 2002; Paolucci 2002, 2006). According to Part 1 of EN-Eurocode 8, topographic amplification of the full elastic spectrum is mandatory for structures of importance above ordinary. An Informative Annex in Part 5 of EN-Eurocode 8 (CEN 2004b) recommends amplification factors equal to 1.2 over isolated cliffs or long ridges with slope (to the horizontal) less than 30° or to 1.4 at ridges steeper than 30°.

EN-Eurocode 8 does not have in Part 1 general provisions for near-source effects. Indeed, directivity effects of the ground motion along the rupture propagation direction are common near the seismotectonic fault rupture, producing at the site a large velocity pulse of long period in the direction transverse to the fault. Part 2 of EC8 (“Bridges”) requires, though, the use of site-specific spectra taking into account near-source effects for bridges located within 10 km horizontally from a known active fault that may produce an event of moment magnitude higher than 6.5. In this respect, it gives a default definition of an active fault as one where the average historic slip rate is at least 1 mm/year and there is topographic evidence of seismic activity in Holocene times (i.e., during the past 11,000 years).

Representation of the Seismic Action Through Acceleration Time-Histories

A dynamic (response-history) analysis, linear or nonlinear, requires as input acceleration time-histories of the ground motion. These time-histories should conform on average with the 5 %-damped elastic response spectrum defining the seismic action.

EN-Eurocode 8 (CEN 2004a) requires as input for a response-history analysis an ensemble of at least three records (or pairs or triplets of different records, for analysis under two or three concurrent components of the action, respectively). It accepts for this purpose artificial, historic, or simulated records.

Artificial (or “synthetic”) records can be mathematically produced using random vibration theory to match almost perfectly the response spectrum defining the seismic action (Gasparini and Vanmarcke 1976). It is fairly straightforward to adjust the phases of the various sinusoidal components of the artificial waveform, as well as the time-evolution of their amplitudes (“envelope function”), so that the artificial record resembles a specific recorded motion; this type of record is called “modified historic” in Part 2 of EN-Eurocode 8. Figure 4 shows seven pairs of 15 s long “modified historic” records, modulated to match the type 1 horizontal response spectrum over ground type C for a PGA on rock of 0.10 g (0.115 g over ground type C); it also compares the resulting spectra with the target spectrum per EN-Eurocode 8.

Note, though, that records which are equally rich in all frequencies are not realistic. Moreover, a motion with a smooth response spectrum, without peaks and troughs, introduces a conservative bias in the response, as it does not let the inelastic response help the structure escape from a spectral peak to a trough at a longer period. Therefore, historic records are favored in EN-Eurocode 8. Records simulated from mathematical source models, including rupture, propagation of the motion through the bedrock to the site, and finally via the subsoil to the surface, are also preferred over artificial ones, as the final records resemble natural ones and are physically appealing. Obviously an equally good average fitting of the target spectrum requires more – appropriately selected – historic or simulated records than artificial ones. Individual recorded or simulated records should be “adequately qualified with regard to the seismogenetic features of the sources and to the soil conditions appropriate to the site” (CEN 2004a). In plain language, they should come from events with magnitude, fault

distance, and mechanism of rupture at the source consistent with those of the design seismic action. The travel path and the subsoil conditions should preferably resemble those of the site. These requirements are not only hard to meet but also may conflict with conformity (in the mean) to the target spectrum of the design seismic action. EN-Eurocode 8 also requires designers to scale individual historic or simulated records so that their peak ground acceleration (PGA) matches on average the value of $a_g S$ of the design seismic action; this requirement may also be considered against physical reality. It is more meaningful, instead, to use individual historic or simulated records with PGA values already conforming to the target value of $a_g S$. Note also that the PGA alone may be artificially increased or reduced, without affecting at all the structural response. So, it is more meaningful to select the records on the basis of conformity of the spectral values alone, as described below.

If pairs or triplets of different records are used as input for analysis under two or three concurrent seismic action components, conformity to the target 5 %-damped elastic response spectrum may be achieved by scaling the amplitude of the individual records as follows:

- For each earthquake consisting of a triplet of translational components, the records of horizontal components are checked for conformity separately from the vertical one (CEN 2005b).
- The records of the vertical component, if considered, are scaled so that the average 5 %-damped elastic spectra of their ensemble is at least 90 % of the 5 %-damped vertical spectrum at all periods between $0.2T_v$ and $2T_v$, where T_v is the period of the lowest mode with a participation factor of the vertical component higher than those of both horizontal ones (CEN 2005b).
- For analysis in 3D under both horizontal components, the 5 %-damped elastic spectra of the two horizontal components in each pair are combined by applying the Square-Root-of-Sum-of-Squares (SRSS) rule at each period value. The average of the “SRSS spectra” of the two horizontal components of the

European Structural Design Codes: Seismic Actions, Fig. 4 Historic records modified to match EC8’s type 1 horizontal response spectrum for ground type C

individual earthquakes in the ensemble should be at least $0.9\sqrt{2} \approx 1.3$ times the target 5 %-damped horizontal elastic spectrum at all periods from $0.2T_1$ up to $2T_1$, where T_1 is the

lowest natural period of the structure in any horizontal direction. If it isn’t, all individual horizontal components are scaled up, so that their final average “SRSS spectrum” exceeds

by a factor of 1.3 the target 5 %-damped horizontal elastic spectrum everywhere between $0.2T_1$ and $2T_1$.

For analysis under a single horizontal component, Part 1 of Eurocode 8 (CEN 2004a) restricts the mean 5 %-damped elastic spectrum of the applied motions not to fall below 90 % of that of the design seismic action at any period from $0.2T_1$ to $2T_1$.

If the response is obtained from at least seven nonlinear time-history analyses with (triplets or pairs of) ground motions chosen in accordance with the above, the relevant verifications may use the average of the response quantities from all these analyses as action effect. The set of seven pairs in Fig. 4 meets this condition for analysis in 3D under two simultaneous horizontal components of ground motion. If less records are used (but not less than three), the most unfavorable value of the response quantity among the analyses should be used.

Spatial Variability of the Seismic Action: Asynchronous Ground Motions

Parts 2 and 4 of EN-Eurocode 8 (CEN 2005b, 2006) require designers to consider the spatial variability of the seismic action in the design of extended structures, namely, of pipelines and multi-support bridges with a continuous deck longer than two-thirds of the distance beyond which the ground motion is taken as uncorrelated. This distance is an NDP with recommended value ranging from 600 m to 300 m for ground type A to D, respectively. Informative Annex D in (CEN 2005b) provides models of the spatial variability of the ground motion and appropriate methods of analysis, including guidance for the generation of seismic motion samples reflecting the probable spatial variability between supports. However, this theory is complex and requires special tools for its numerical implementation and special site data for the determination of the model parameters. So, the code allows using a simplified approach to take into account the spatial variability of seismic motions along

the bridge. So, Part 2 of EN-Eurocode 8 (CEN 2005b) also gives a simplified method to account for such effects in design. This may be achieved by superimposing to the seismic action effects from an analysis that neglects the spatial variability of the motion the effects of postulated static relative displacements of the supports in the same or in the opposite direction, which are a function of the peak ground displacement from Eq. 15 and the aforementioned distance beyond which the ground motion may be considered as uncorrelated.

Summary

The six parts of the first European Standard for seismic design, assessment, and retrofitting of structures were published from 2004 to 2006 as EN-Eurocode 8. In this European structural design standard, the seismic action for which new structures are designed for the Ultimate Limit State (life safety performance) is the “design seismic action”; it is determined as the product of the reference seismic action times the importance factor of the structure. The return period of the reference seismic action is chosen by the country, which retains the authority to set the safety level in its territory, taking into account economic aspects. Seismic zoning is expressed in terms of the peak ground acceleration on rock, to which the elastic acceleration response spectrum is anchored. This spectrum has regions of constant spectral pseudo-acceleration, pseudo-velocity, and displacement, the extent of which is decided by the country depending on the earthquake magnitude, as a function of the type of soil in the top 30 m and the geologic conditions underneath. Five standard types of ground are defined; for each one of them, two types of indicative spectral shapes are given: one for a surface magnitude above 5.5 and the other for below that limit. The indicative spectral shapes have been developed on the basis of strong motion data from the south of Europe. The peak ground displacement is given as a function of the peak ground acceleration, along with guidance for the construction of the displacement response spectrum on the basis of the peak ground displacement and the

acceleration response spectrum. Vertical response spectra are introduced and indicative shapes are given. Elastic response spectra are utilized to derive reduced design spectra for conventional force-based design or to generate/adopt acceleration time-histories for nonlinear dynamic analysis. For the design of new buildings, towers, chimneys, tanks, silos, or pipelines, a second seismic action is introduced for the damage limitation state (for protection of property or operation of the facility under a frequent or occasional event). Three limit states (performance levels) are introduced for the assessment and retrofitting of existing buildings: damage limitation, significant damage, and near collapse. The country may set the levels of seismic action for which these limit states are checked or may leave the decision to the owner.

Introduction

Earth Observation (EO) images can be very useful in a wide range of human activities, from the understanding of global phenomena to decision-making processes. Mostly, the exploitation of the acquired images in the area and period of interest is still performed by visual interpretation. In this way, experts in EO sensing and application domains (e.g., seismology, agriculture, meteorology, forestry, etc.) add their knowledge after their analysis. When the experts' interpretation is concluded, only a minimal part of the data, the portion containing the useful information, is kept, while the remaining part can be discarded. However, this process is highly demanding in terms of costs, human effort, and time. Therefore, it cannot be performed on a regular basis, which

involves the loss of information potentially useful for research activities, service providers, and final users. The consequences of such a lack of information flow might be very significant as it may prevent operators who rely on EO data from making the right decisions, and leave relevant phenomena undetected or to be discovered too late. In this context, important support can be provided by feature extraction methods, more automated and direct procedures for the extraction of information from images. Relying on "intelligent" automatic techniques, these methods support the image interpreters in discovering the essential elements of information in an image. Sometimes the extracted feature is already the final object of interest, for example, an oil spill in the ocean or a thermal anomaly. In other cases, it consists of intermediate processing aiming at generating a new representation of the image data where particular statistical or geometrical characteristics are highlighted.

Pixel averaging is one of the simplest techniques used when extracting features in image processing. This means replacing a box of pixels with a single pixel. In particular, the value of the pixel will be obtained by computing the average of the values of all the pixels belonging to the considered box. We can say that the new pixels' values are features of the original image, representing its information content in a more compact way. From the example given, it may be understood that feature extraction can also play another crucial role in the context of image

processing and, more in general, of pattern recognition: dimensionality reduction. In fact, dimensionality reduction can be a fundamental step in the implementation of many classification or retrieval problems. If we are forced to work with a limited quantity of data, as we often are, then increasing the dimensionality of the space rapidly leads to the point at which the data is very sparse, therefore providing a very poor representation of the mapping. To describe the extraordinarily rapid growth in the difficulty of problems as the number of variables (or dimension) increases, the phrase “the curse of dimensionality” has been coined by Richard Bellman (1957). Reducing the number of input variables can lead to improved performance for a given data set, even though information is being discarded. The mapping is better specified in the lower-dimensional space, which more than compensates the loss of information.

An Overview of Feature Extraction Techniques

According to the type of satellite data to be analyzed (SAR, optical/multispectral, time series) and the considered application, different approaches can be used for feature extraction:

Spatial and Contextual Features

Spatial and contextual features try to synthesize the information contained in neighboring pixels with respect to a pixel under examination. Different contextual descriptors can be defined. One of the earliest and most important techniques used to express textural and tonal variations in a remotely sensed image data is the one based on the gray-level co-occurrence matrix (GLCM) (Haralick et al. 1973). The GLCM is the core of a mathematical framework capable of representing the distance and angular relationships among the pixels over an image subregion of a specified size. Each element of the GLCM is a measurement of the probability of occurrence of two gray scale values separated by a given distance in a given direction. Several quantities

can be computed from the elements of the GLCM which describe quantitatively the textural behavior of the subregion considered. Another approach for textural characterization relies on probabilistic modeling. Markov random field (MRF) models fall under this category and can be quite successful for texture modeling (Cross and Jain 1983). They capture local characteristics of an image considering regional patterns and by assuming a local conditional probability distribution. Spatial feature extraction can be based on multichannel filtering as well. The image is decomposed into a set of sub-bands which are calculated by convolving it with a bank of linear filters, nearly uniformly covering the spatial-frequency domain, followed by some nonlinear procedures. Gabor filters can be an example for this type of techniques (Jain and Farrokhnia 1991). Mathematical morphological filters should also be mentioned for the detection of textural features. In this case, the extraction is obtained by performing shape-oriented operations, like openings and closures, based on set theory (Soille 2003).

Transform Domain Features

An image transform is a mathematical operation that re-expresses in a different, and possibly more meaningful, form all, or part of, the information content of a multiband or gray scale image. One of the most used transform methods for feature extraction is the principal component analysis (PCA) (Singh and Harrison 1985) where a multispectral set of m images is re-projected in terms of a set of m principal components. Two particular properties exist: the components are extracted for decreasing variance, and the principal components are statistically unrelated or orthogonal. For multiband images, the first PCA components can represent effective features to be used in the operational scenarios to be considered, as they reveal the structure behind the correlation of the variables. Indeed no linear combination (i.e., weighted sum) of the original bands can contain more information than is present in the first principal components.

An alternative approach considers harmonic analysis, a field of mathematics that studies the

F

Features Extraction from Satellite Data, Fig. 1 $1,500 \times 1,500$ pixels synthetic interferogram's example (*left*) and reconstructed one by means of first 500 DWT components (*right*)

representation of functions as overlapping of fundamental waveforms. It is known that a multivariate function f can be well approximated by the linear combination of the elements of a given basis. This type of operation is called harmonic analysis. When harmonic analysis is applied to image data, the discrete image can be seen as a two-dimensional signal, and it is possible to consider a set of mathematical tools that perform a transformation suitable to extract some features otherwise difficult to be identified. This can be done by means of particular functional operators like the DFT (discrete Fourier transform) and the DWT (discrete wavelet transform). Both the transforms express the signal as coefficients in a function space spanned by a set of basis functions. The basis of the DFT is complex exponential functions, representing sinusoid functions in the real domain, and the multiplying coefficients are also complex numbers. The basis of the DWT is scaled and shifted versions of a mother wavelet real-valued function. In this case, the coefficients have real values. Low pass filtering of the DFT and DWT transformed images can be considered for the extraction of low spatial-frequency features (Picchiani et al. 2012). See an example of application in Fig. 1.

Advanced Nonlinear Techniques

Linear techniques such as PCA may be unable to capture nonlinear correlations so they may fail when dealing with highly complex data. One way of performing a nonlinear extension is to lift the input space to a higher dimensional feature space by a nonlinear feature mapping and then to find a linear dimension reduction in the feature space (Scholkopf et al. 1999). Kernel techniques allow such nonlinear extensions without explicitly forming a nonlinear mapping or a feature space, as long as the problem formulation only involves the inner products between the data points and never the data points themselves.

Neural networks can also be applied to effectively extract nonlinear features from data. For example, this can be obtained by using Autoassociative Neural Networks (AANN) (Bishop 1995). These are multilayer perceptron (MLP) networks which are trained to the purpose of reproducing the inputs in the output layer (Fig. 2). This means that the targets used in the training phase are simply the input vectors themselves. Hence, the net is said to perform autoassociative mapping (autoencoder). One of the hidden layers of the AANN, known as the bottleneck layer, is characterized by a number of units significantly lower than the number of

Features Extraction from Satellite Data,

inputs/outputs. If during the training phase the actual outputs of the network are capable of resembling those desired with a satisfactory level of error, this implies that the bottleneck layer is capable of providing, in a lower dimension, good representation of the input. In Fig. 3, two nonlinear principal components calculated from a Landsat image are shown. SOM (Self-Organizing Maps) represent another possibility of performing feature extraction using neural networks. The SOM map or Kohonen map is a two-layered network. The first layer of the network is the input layer. The second, called the competitive layer, is usually organized as a two-dimensional grid. All interconnections go from the first to the second layer. In the training phase, the data are presented in a random order to the network. All the nodes in the competitive layer compare the inputs with their weights and compete with each other to become the winning unit with the lowest difference. After that, the weights of the winning neuron and of its neighbors are adjusted towards the input vector. The magnitude of change decreases with time and with distance from the winning neuron. In this way, a SOM can automatically form 1D or multidimensional maps of the intrinsic features of the input data and reorganize them in several output clusters/classes.

Feature Extraction in Seismological Applications

There are several features of interest for seismology that can be extracted from Earth Observation data. A major category regards the thermal anomalies. Due to pressure increase and subsurface degassing activities, a sudden rise in land surface temperature (LST) can characterize the area of interest prior to an earthquake. The detection of such thermal changes can be very important in an effort to predict earthquake activities and provide time to give suitable warnings. Appropriate satellite data with thermal bands can be used to extract this kind of feature from multi-temporal images. Moreover, besides land surface, due to the release of gas emissions causing a local greenhouse effect, anomalies can also be detected in the concentration of some gases in the atmosphere. Another important application is focused on retrieving information about the surface deformation once earthquake occurs. Earthquakes produce static displacements of the ground that can be observed near the fault that slipped during a seismic rupture. The measurement of such displacements is a crucial issue in seismotectonics, as it gives insight into the geometry of the ruptured fault and the energy released by the earthquake. Such measurements are generally performed using geodetic techniques that can

F

Features Extraction from Satellite Data, Fig. 3 Original Landsat image (*left*) and two computed nonlinear principal components (*center and right*)

only provide a sparse covering, because the areas of coseismic ground displacement are not known a priori. Satellite imagery is naturally suited for such measurements, because it regularly provides comprehensive and detailed images of the ground with high radiometric and geometric quality. The displacement field can be measured by the comparison of images acquired before and after the event. Both InSAR (interferometric SAR) and optical data can be exploited for this type of investigation. Other effective uses of Earth Observation data for seismology are connected with disaster management. In the management of a seismic event to immediately draw up a draft, damage map of the stricken urban areas is of great importance in order to organize civil protection interventions. Remote sensing can provide

valuable items of information in this respect, thanks to its synoptic capability, in particular when the seismic event is located in remote regions or a failure affected the main communication systems. Both optical and radar sensors can be exploited for the extraction of this type of feature. Despite the great potential provided by Earth Observation data for supporting operational activities in the field seismology, it has been pointed out that the level of automatic data processing is mostly inadequate with “still too much manual labour and author arbitrariness” (Tronin 2010). This is not the case when considering the estimation of tectonic parameters from SAR interferometry where feature extraction, according to innovative technologies based on neural networks, can be fully automated.

Automatic Tectonics Parameter Retrieval from InSAR Data

Until SAR interferometry (InSAR) broke out in the beginning of the 1990s as an effective technique for analyzing a seismic event, most of the measurements used for this kind of study were based on the ground recording of the waves generated by the earthquake. In fact, such data are still very helpful in providing information on the location or the magnitude of the seismic event. However, these measurements may not be sufficient if a more accurate estimation of the earthquake parameters, such as the fault depth, is desired.

The first application of the InSAR technique for the investigation of the characteristics of a seismic event regarded the Landers Earthquake (Massonet et al. 1993). The innovative method was capable of providing effective information on the generated displacement field. After that, a few studies using the same approach were conducted on various both strong (Kobe, Japan, 1997; Izmit, Turkey, 1999; Hector Mine, CA, USA, 2000; Denali, AK, USA, 2002; Bam, Iran, 2003; Sichuan, China, 2008) and moderate (Colfiorito, Italy, 1997; Abruzzi, Italy, 2009) earthquakes. It was discovered that, thanks to its ability to generate a distributed map of the total strain release, in many cases the InSAR technique was the only one capable of providing the investigators with a higher level of information.

In fact, by comparing pre- and post-event SAR data and calculating the interferometric phase, InSAR can reconstruct the coseismic surface displacement field with a centimetric accuracy. The potential of InSAR data can also be combined with GPS measurements and with more standard seismological and geophysical data, such as strong motion records, for the assessment of normal fault models, generally stemming from the Okada formulation (Okada 1985). In particular, for modeling radar interferometric data, specific software packages can be used to calculate the displacement components (Feigl and Duprè 1999) which, in an elastic half space, are the expression of the seismic source at the surface.

Features Extraction from Satellite Data, Fig. 4 Fault geometry and symbols

In fact, the inverse problem is of great interest. This means the attempt to retrieve, also in a quantitative way, the source parameters starting from the knowledge of the InSAR surface displacement field. In particular, some useful information to define the fault geometry (dip and strike angle; width and length), the extension of the rupture, and the slip distribution on the fault plane can be obtained.

For the estimation of the desired parameters, two main steps have to be carried out after the computation of the interferogram. The first one regards the dimensionality reduction of the data. The second one is the design of a suitable retrieval algorithm. With reference to Fig. 4, besides the length and the depth of the fault, tectonic parameters that can be estimated are the following: the slip vector $U = [U_1, U_2, U_3]$, which represents the movement of the hanging wall with respect to the foot wall signed such that U_1 is positive for left lateral strike slip, U_2 is positive for thrusting dip slip, and U_3 is tensile slip; the strike (α), which is the clockwise angle between the direction of the fault trace and the North–South one; and the dip (δ), that is, the angle between the fault plane and the surface. Another possibility, optionally complementary to parameter estimation, is the classification of the fault. The main classes of normal fault, strip-like fault and reverse fault (thrust), are typically considered.

Dimensionality Reduction of the Data

Data dimensionality reduction is one of the key issues in retrieval and classification problems. In this specific case, it is certainly not appropriate to feed a classifier or a parameter estimator with all the DN numbers forming the interferometric image. In such a context, a standard technique for performing dimensionality reduction is to sample the interferogram with an adequate frequency. A better performance can be obtained considering the combination of two techniques for feature extraction. In particular, the first processing step relies on the harmonic analysis, and in the second, the AANN is applied. Such an approach leads to the determination of a considerably reduced number of components for the interferogram representation without involving the training of huge AANN topologies. An interferogram with a dimension of $1,500 \times 1,500$ pixels can effectively be represented by a vector of 50 components if the chaining of the AANN and the DWT is applied (Picchiani et al. 2012).

Classification and Retrieval Using Neural Networks

Once the data dimensionality reduction has been performed, and the interferogram is represented by means of a vector expressing a limited number of significant feature values, an algorithm is necessary to transform such a concentrated information content into a set of values to be associated with the desired quantities. Such desired quantities may either be values of tectonic parameters or probabilities of belonging to a specific fault class. In both cases, the problem is rather complex due to its inherent nonlinearities. For this reason, the use of neural networks can be considered as they are recognized as a powerful tool for inversion procedure in remote sensing applications (Stramondo et al. 2011).

Among various topologies, multilayer perceptrons (MLPs) have been found to have the best suited topology for classification and inversion problems and can also be used in this case. These are feedforward networks where the input only flows in one direction, towards the output, and each neuron of a layer is connected

to all neurons of the successive layer but has no feedback to neurons in the previous layers.

Compared to other methods, the use of NNs is often effective because they can simultaneously address nonlinear dependences and complex physical behavior with reduced computational efforts and without requiring any a priori information (Bishop 1995). Moreover, NNs learn the input–output relationships exclusively from the training patterns; therefore, no explicit expression addressing the interactions between the parameters of interest is needed with such an approach.

In the training phase, the weights (internal parameters of the network) are progressively adjusted to enable the approximation of the needed functional relationships. The performance of the algorithm is monitored by an error (or cost) function which has a nonlinear dependence on weights. Once the error is minimized, the trained MLP performs the desired mapping of input space onto output space.

As far as the source mechanism classification is concerned, the training and validation sets can be created through the generation of synthetic differential interferograms. Such a generation can be performed using a forward model computing the surface deformation (the displacement vector) associated to specific values of the given fault parameters. For this purpose, the Okada formulation can be considered as it explains, in a close analytic form, the surface deformation due to a seismic event by a dislocation model in an elastic half space. The data set is obtained by running the forward model varying the values of its parameters appropriately all along a certain range (see Fig. 5). In the classification case, the output layer of the network consists of three units each associated with one of the three considered fault mechanisms. The network is trained in order to give the value one to the unit corresponding to the desired type of mechanism and the value zero to the other two units. In the parameter retrieval case, the output of the network is formed by the desired quantities. Once the network is trained, the technique performs in a fully automatic mode, providing the fault classification and/or the estimation of the fault parameters in real time.

from the simulated data set generated by means of RNGCHN software. *Top*: normal fault; *middle*: strike slip fault; *bottom*: reverse fault

Summary

The contribution introduces the feature extraction techniques and explains the rationale for their use especially in the field of image processing. The main feature extraction approaches are briefly reviewed and an insight of the most important applications for the analysis of earthquakes with Earth Observation data is given. The complete methodology addressing the problem of the

estimation of tectonic parameters from SAR interferometric data is described.

Introduction

The spatial and temporal distribution of earthquakes sizes near and around volcanoes can be characterized through the well-known frequency-magnitude distribution:

$$\log N = a - bM \quad (1)$$

Frequency-Magnitude Distribution of Seismicity in Volcanic Regions, Fig. 1 Average magnitude of completeness and b -value for the data compiled by Observatorio Vulcanológico y Sismológico de Pasto (OVSP, Servicio Geológico Colombiano) at Galeras Volcano, Colombia. *Left*: Data for the period 2004–2013.

Total number of earthquakes used is 5,858. The *solid line* shows a least squares best fit for the linear part of the frequency-magnitude distribution (FMD). The *insets* show histograms of magnitudes, with bins equal to 0.1. *Right*: Data for the period 2008.3–2010.6. Total number of earthquakes is 1,384. Conventions as in *left* panel

where N is the cumulative number of earthquakes with magnitude $\geq M$ and a and b are constants representing the seismic productivity of a region and the slope of the linear part for the distribution, respectively. This is a well-known power law (Gutenberg and Richter 1944) that is applied herein.

Earthquake catalogs compiled by volcano observatories around the world are commonly used to estimate b values and map their spatial distribution. From Eq. 1, it is evident that earthquake magnitude plays a fundamental role and is important to mention that its computation may vary from one catalog to another. Firstly, different magnitudes have been traditionally calculated at different observatories (duration magnitudes, M_D , and local magnitudes, M_L , are most common) and secondly, detection capabilities vary because of the different network configurations and equipment. The magnitude of complete detection or magnitude of completeness (M_c) is the value above which the catalog is considered to be approximately complete (Fig. 1).

In a practical way M_c can be estimated by visual inspection of any of the forms of the FMD. For example, in Fig. 1 the FMD for earthquakes at Galeras Volcano, Colombia, is shown. The histogram of the number of events versus

magnitudes shows a slightly skewed distribution with a right tail and a maximum that occurs in the range $0.7 \leq M_L \leq 0.9$, a first indication of the probable value of M_c in the catalog. Another estimate of completeness may be obtained by finding the maximum curvature of the FMD using a combination of 90–95 % confidence in the curvature (derivative) estimation. Indeed, this procedure gives $M_c = 0.8$ for the whole catalog implying that earthquakes with $M_L < 0.8$ are probably not being always detected. Inspection of a curve of cumulative number of earthquakes versus time revealed that during 2004–2013 rates of seismicity at Galeras varied, most likely because of occurrence of swarms, groups of earthquakes with similar magnitudes that occur closely separated in time and not associated to a mainshock. The period 2008.3–2010.6, however, exhibited a fairly stable behavior and the corresponding FMD did not vary (Fig. 1, right panel). The data for both time periods follows fairly well a Gutenberg-Richter law and the difference in average b -values between both datasets is small. Earthquake catalogs usually are culled at the M_c value to ensure that the dataset is mostly complete. The linear part of the FMD can be fit by a least squares procedure to obtain a straight line with negative slope.

The slope is called the b -value and it represents the average size distribution of earthquakes.

Because the b -value is related to the mean magnitude in a given region, it is important to spatially map its distribution in both volcanic and tectonic environments because of the possible relationships with the state of stress in the crust. When calculating the spatial distribution of b , one must consider (1) the calculation method, which can either be maximum likelihood or weighted least squares, and (2) the parameters of the gridding scheme and the number of events to sample around each node of the grid (Wiemer and McNutt 1997).

To calculate the b -values and estimate their spatial distribution, it is necessary to create a grid in two or three dimensions. As a general rule the node separation should be proportional to the formal errors in the spatial parameters of the earthquake locations. Regarding the sampling mode around each node, there are two possibilities: either selecting a constant number of events within circles of variable radii or selecting a variable number of events inside circles of constant radii. In both methods the sampling volume has the shape of a cylinder, with its base centered on a particular node of the grid. If the calculation takes place in map view, the cylinder will be vertical, but if the calculation is on a vertical cross section, the cylinder will be horizontal, with variable height and radius depending on the sampling method. In this way the cylinders can be coin shaped or pipe shaped. If the grid is for a 3D region, the sampling volumes will be spheres.

Within each cylinder the b -value is calculated from the FMD obtained from the sample and in this case one can either assume a constant M_c (usually equal to the minimum magnitude within the sample) or calculate the FMD locally. It is usually a good practice to calculate b -values using both methods and trying several sampling schemes to test the stability of the results.

The estimation of b -values has been an active research area over the last two decades and here a description of results for volcanoes around the world is presented, then the possible implications for magma processes are summarized and the

body of accepted knowledge on seismic b -values near volcanoes is presented. Finally, a short case study on one of the most active volcanoes is shown to exemplify applications of the technique and to describe some possible implications for volcano and earthquake hazards and risk.

Seismic b -Values at Volcanoes Worldwide

The distributions of seismic b -values at depth have been studied (by spatial mapping mostly) at a number of volcanoes around the world using a variety of catalogs. A compilation of results of 2D and 3D mapping at 16 volcanoes is presented (Table 1).

Table 1 highlights that b -value anomalies are common regardless of the type of volcano, configuration of the seismograph network, magnitude scale used, or amount of earthquakes in the dataset. The pattern of the anomalies varies from place to place, however (Wyss et al. 1997), and it is established that, with no exception, volcanic areas exhibit irregularly shaped volumes of anomalously high b -values surrounded by regions of normal-to-low b -values (Wiemer and McNutt 1997; Wiemer and Wyss 2002). From Table 1, it is observed that there is notable spatial variability of b , with several volcanoes having more than one region of increased b -values. There is variability in the computed b -values as well, with b -anomalies in the range $1.0 < b < 3.0$, and although it would seem appealing to compare these values among volcanoes, conclusions drawn from such task would not be solid, because of the different magnitude scales used. For instance, the b -values of ~ 1.55 reported for shallow anomalies at Mt. St. Helens and Nevado del Ruiz are not necessarily comparable.

It is reasonable to assume that mineral stabilization (formation of crystals) in magmas takes place at depth within the magma chamber and that exsolution of gas and vesiculation might occur at shallower levels. The mineral and volatile species and types of magmas studied vary and thus the calculated depths for stabilization of minerals or gas exsolution and formation of

Frequency-Magnitude Distribution of Seismicity in Volcanic Regions, Table 1 Main features of *b*-value anomalies and data on mineral stabilization and gas processes at volcanoes around the world. Reported and calculated stabilization pressure values from various authors are converted to pascals (Pa, $\text{N/m}^2 = \text{m}^{-1} \cdot \text{kg} \cdot \text{s}^{-2}$) or megapascals ($\text{MPa} = 10^6 \text{ Pa}$) as this is the SI derived unit for pressure or stress

^aValues for b -anomalies and their locations are taken from results of 3D mapping and vertical cross sections, where reported

^bDuring July 27, 1995, to December 31, 1997, the Alaska Volcano Observatory reported over 2,500 earthquakes located in the general area Martin-Mageik-Trident-Katmai Caldera. The b -values reported in the table were estimated from Fig. 6 (Jolly and McNutt 1999)

^c b -values at Martin-Mageik region may include data from swarms in Sept. 1996–April 1997. Values calculated pre- and post swarm were in the range $0.92 < b < 0.98$

^d M_p is a “preferred magnitude” chosen hierarchically and defined in the data description prepared by F. Klein for distribution of the earthquake catalog at Hawaii. Mostly equal to M_D and in few cases equal to M_L

^eMagnitudes were recalculated by regression equation from M_D to M_L using a sample of earthquakes simultaneously recorded by broad band and short period subnetworks

^fBridges and Gao report a second, deeper b -value anomaly ($b \sim 1.6$) detected at roughly 12 km depth southeast of Makushin, but it was deemed statistically insignificant

Frequency-Magnitude Distribution of Seismicity in Volcanic Regions,

Fig. 2 Histogram of b -value anomaly centroid depths beneath volcanoes

vesicles: For Mt. Etna, Italy, Trigila et al. (1990) report a range of 85–225 Mpa pressure range for Plagioclase stabilization in basaltic lavas and it has been suggested that the feeding system for magmas at Etna may be composed of different reservoirs; at the Katmai cluster, USA, Coombs and Gardner (2001) estimated a range of 40–100 Mpa for Plagioclase stabilization in andesite-dacite-rhyolite magmas erupted during the 1912 eruption from Novarupta; at Redoubt, USA, Gerlach et al. (1994) suggested that SO_2 is stored as vapor at 6–10 km depth in the magma before the 1990 eruptions and perhaps at shallower levels (4–6 km) prior to the 2009 eruptions (Coombs and Bacon 2012); at Nevado del Ruiz, Colombia (Stix et al. 2003), it has been suggested that ascent of volatile-bearing magma took place from 9 to 15 km depth and remained at shallow residence depth of <3 km; at Mt. Pinatubo, Philippines, estimation of volatile contents in the range 5.1–6.4 % suggested a vesiculation depth of 6 km for pre-eruptive magmas and stabilization of olivine at 2.2 kbar or a depth of magma storage in the range 7–11 km was also inferred (Bernard et al. 1996); at Galeras, Colombia (Stix et al. 1997), gas exsolution might have taken place at 20–100 Mpa or 0.8–3.9 km depth; and at Makushin, USA, scoriae within mafic ignimbrite layers were analyzed (Goldberg 2010) and a stabilization pressure of pyroxenes

in a range of 1.26–2.12 kbar has been suggested. Evidence from Geology, Petrology, and Geochemistry thus indicates that several processes take place at different depths beneath volcanoes.

From Table 1 it is also evident that seismicity studies have also revealed that beneath many volcanoes, b is anomalously high at different depths. All volcanoes listed (17) exhibit b -value anomalies embedded in an otherwise region of normal-to-low b -values. With respect to the distribution of b -values at depth, most volcanoes studied (16, b -values at Yellowstone were not mapped at depth) have at least one anomaly, and 11 out of 16 volcanoes exhibit more than one anomalous region. The centroid depths for b -value anomalies vary in the range 2–19 km and their distribution are shown in Fig. 2.

From Fig. 2 it is evident that, in many cases, volcanoes exhibit two anomalies at different depths: one shallow anomaly is common in the range 2–4 km and a deeper one appears in the range 7–8 km. The first anomaly range includes not only the depth at which volatiles in magma with 4 % weight fraction may start to exsolve but also the region where the existence of open cracks is plausible. At depths similar to the range 7–8 km, alternate geophysical evidence and geology studies support the nearby presence of magma bodies. At Galeras Volcano, Colombia, the shallow plumbing magmatic system has

been conceived as a vertically elongated feature such as a reservoir extending down to 5–6 km depth or a fractured plug beneath the active cone that overpressurizes and acts as the source of material during Vulcanian explosions (Stix et al. 2003) and a deeper magma reservoir below 4 km depth.

Regarding the cause of anomalous b -values, there is general agreement that several factors may be involved; these are summarized as follows:

Accepted Knowledge on Seismic b -Values at Volcanoes

- That the frequency-magnitude distribution is related to the heterogeneity (degree of cracking) in the upper crust and can be appropriately measured by a power law expressed in the Gutenberg-Richter law. The parameters of this law are understood as the seismic productivity of the volume (“ a -value”) and the mean magnitude of the linear part (“ b -value”).
- Estimating the b -value is equivalent to estimating the mean magnitude and it is reasonable to assume the mean magnitude as proportional to mean crack length.
- Heterogeneity in volcanic areas can be pervasive and may be related not only to the nature and amount of cracking that the magma system or volcano edifice may have but also to the nature of rocks and deposits that form volcanoes, usually a combination of hydrothermally altered lava flows and pyroclastic deposits.
- Although volcanic areas were usually reported as having higher-than-normal b -values, with respect to a “global” average of $b = 1.0$, it is now known that instead, volcanoes exhibit regions of anomalously high b -values within a “normal” crust.
- That magma (molten rock inside the earth) cannot support shear stresses and therefore earthquakes cannot occur there. b values give information on faults and fractures in the vicinities of magma chambers. The resolution of earthquake locations may not be still enough to reveal details on the configuration of magma systems, although the concept of complex configurations in the magma and plumbing systems beneath volcanoes is generally accepted.
- That factors that may contribute to variations in b are:
 - (a) To increase b :
 1. Increase in material heterogeneity. At volcanoes this can be associated to increase in cracks, caused by vesiculation and fragmentation of ascending magma, processes that likely take place at relatively shallow levels (roughly 4 km depth for magmas with 4 wt. % H_2O).
 2. Increase in pore pressure caused by magma nearing groundwater (which would imply decreasing the effective stress). This process may also likely take place at relatively shallow levels.
 3. Increase in the thermal gradient. Quite possible near magma systems or intrusions, because magmas may reach temperatures near 1,200 °C.
 - (b) To decrease b :
 1. Increase in applied shear stresses. Difficult to model this near volcanoes, but plausible along the faults that are common in volcanic areas. Zones of lower-than-normal b -values have been associated to regions of high stress load and therefore areas where large earthquake nucleation could take place. In this perspective, seeking for regions of lower-than-normal b -values is just as important and may have hazard implications.
 2. Increase in effective pressure or decrease in pore pressure. Could be conceivable during or after volcanic eruptions.
 - (c) Either to increase or decrease b :
 1. Changes in the configuration of the detection network or changes in analyses procedures. These may introduce artifacts in the catalog. For example, a change in the way magnitudes are determined may cause a “stretching” of the magnitude scale, offsetting b toward lower values.

It has been suggested that processes such as vesiculation, fragmentation, and magma intrusions can affect the crack distribution beneath a volcano. Gas exsolution and subsequent bubble nucleation and growth inside magmas take place under colossal pressure conditions. Bubbles can increase in numbers and accumulate near the top of magma reservoirs increasing pressure on the host rock and facilitating cracking. Also, magmas intrude through fractures and weak zones of the crust and this process may cause new cracks and fracture propagation thus changing the homogeneity of the rock masses.

From Table 1 a scatter plot of the centroid depths for b -value anomalies versus the pressure at which mineral stabilization and/or gas exsolution might take place or the estimated depth for magma storage (from Petrology, Geochemistry, and Geology data) was built. Errors in the centroids of b -value anomalies were taken as the maximum and minimum observable extents at depth from published and authoritative material. Results are shown in Fig. 3.

Based on Fig. 3 (right panel), a positive relation between the depth of deeper b -value anomalies and the magma process beneath volcanoes is mildly revealed for a group of eight volcanoes: Mammoth Mt. (Long Valley Caldera), Nevado del Ruiz, Mt. St. Helens, Katmai-Novarupta, Redoubt, Mt. Pinatubo, Mt. Etna, and Miyakejima. These include diverse-sized volcanic systems from a variety of geological environments: six continental arc volcanoes (formed above oceanic-continental subduction zones), a hot spot volcano, and an island arc volcano (formed above oceanic-oceanic subduction zone).

b -Values at Galeras Volcano, Colombia, and Implications for Earthquake Hazard and Risk

Galeras Volcano, one of the most active volcanoes in Colombia, looms over the city of San Juan de Pasto (pop. 400,000) which lies just a few kilometers east of the active crater. Not only have repeated eruptions of Galeras affected life and property over the years and volcanic

processes do represent a significant hazard for the region (INGEOMINAS 1997), but also earthquakes possibly associated to volcanic-tectonic interactions have caused damage and fatalities in recent times. Thus, seismically characterizing the region near Galeras is of relevance and mapping of b -values offers the opportunity to identify zones of smaller-than-average earthquakes as well as regions where relatively large earthquakes are typically produced.

Using preliminary earthquake locations between September 1995 and June 2002, a first approach to spatially map the earthquake size distribution around Galeras was taken (Sánchez et al. 2005). Their results of 3D mapping readily allowed to identify a prominent high b -value anomaly beneath the active crater and vertically elongated down to 5 km depth which was inferred to be the region adjacent either to the volcano's conduit, the shallow magma reservoir, or alternatively the remnants of a semi-brittle intrusion. In map view, this anomalous feature was basically surrounded by regions of normal-to-low b -values. Of particular interest here is the cluster of earthquakes located northeast of Galeras, where the source of three swarms that included damaging earthquakes ($M_L \leq 4.7$) was identified during 1993–1995 (April 1993, November–December 1993, and February 1995). This source falls within a region of low b -values detected preliminarily in the early 2005 study (Fig. 4).

Recent data for Galeras has been analyzed and the catalog of earthquakes for the period 2004–2013 was used to spatially map b -values using both the entire catalog data and a subset of it (2008–2010), during which seismicity rates were observed to be fairly stable. Results are presented in Fig. 5. In map view the region north-northeast of Galeras still appears as a region of low b -values and remains as a source of moderate-sized earthquakes (a sequence of four $4.6 < M_L < 4.7$ earthquakes occurred there during mid 2005). The active crater region remains highly productive, but it does not show as a zone of smaller-than-average earthquakes, on the contrary, falls within an area of low b -values and was the source of two separate $4.6 < M_L < 4.7$ earthquakes in 2006 and 2010.

Frequency-Magnitude Distribution of Seismicity in Volcanic Regions, Fig. 3

Scatter plots of the depths of *b*-value anomalies observed at volcanoes versus pressure conditions calculated for gas exolution or mineral stabilization (from Geology, Petrology and Geochemistry data). Many volcanoes from Table 1 exhibit more than one *b*-value anomaly usually at different depths. *Left*: Centroid depth of “shallower” anomalies. *Right*: Centroid depth for “deeper” anomalies. Thick black lines in both panels show a basic linear fit ($R = 0.0$ for the data on the left panel, $R = 0.5$ for data on the right panel)

It is conceivable that once a volcano or a region of the crust has acquired a given crack distribution, this is difficult to change and thus the distribution of *b*-values would be fairly constant through time. At volcanoes, however, multiple intrusions are common and therefore a much fractured host rock may be plausible. For example, the well-recorded earthquake swarms beneath the Teishi Knoll Volcano (off Ito, Japan) were associated to magma intrusions and the detected change of *b*-value with time

was attributed to new cracks (Wyss et al. 1997). Thus, changing the heterogeneity of the shallow crust near volcanoes, or the difficulty in causing changes in such systems, could be viewed as a matter of time scale. The results described for Galeras could signal a change in conditions of the shallow crust near the active crater.

As it can be seen in Figs. 4 and 5, the Galeras region is crossed by several faults in a general southwest-northeast direction and the volcano

Frequency-Magnitude Distribution of Seismicity in Volcanic Regions, Fig. 4 Map of b -values in the Galeras region for the period 1995–2002. High b -values are mapped as regions of hot colors (red-orange), regions of low b -values appear as areas of cold colors (blue). Dots: earthquake epicenters. Triangle: active vent. Continuous

black lines: faults. Thick red contour: limits of San Juan de Pasto. Swarms of damaging earthquakes were produced between 1993 and 1995 in the area of low b -values northeast of the volcano (Modified from Sánchez et al. 2005)

Frequency-Magnitude Distribution of Seismicity in Volcanic Regions, Fig. 5 Maps of b -values in the Galeras region. *Left*: period 2004–2013, using all earthquakes with $M_L > 0.8$. Relatively large earthquakes ($4.6 < M_L < 4.7$) occurred in 2006.16 (near the crater), 2010.64 (just east of the crater), and during 2005.64–2005.65 (north-northeast of the crater, four earthquakes). *Right*: period 2008–2010, during which the

seismicity rate was fairly constant. The different b -values in the western portions of Galeras between the different datasets may be an artifact caused by the different sampling around each node, necessary because of the lower number of earthquakes in the shorter period 2008–2010. The region of interest, northeast of the active crater remains mostly unchanged. Conventions as in Fig. 4

itself is spatially related to these structures, particularly to the splay of the two faults near the active crater. It is conceivable that magma has used faults as pathways to the surface, making

this area a particularly complex one in terms of stresses and earthquakes.

Interestingly, the area southeast of the volcano which shows persistently as a region of

very low b -values has not produced relatively large earthquakes damaging to San Juan de Pasto.

The concept that faults include both locked and unlocked portions, the former conceived as asperities that resist sliding and the latter known as creeping segments, implies that asperities are regions that accumulate stress whereas in creeping segments stresses are constantly relieved. The distribution of b -values near active faults has been successfully used to mark the sites of asperities and creeping segments along faults (Wiemer and Wyss 2002), with areas of low b -values signaling asperities and areas of higher-than-normal b -values representing creeping segments. Volcanic regions are always affected by active faults, and considering that moderate-sized earthquakes have been detected near the volcano, it is reasonable to assume that near Galeras Volcano the distribution of b -values may help in identifying areas of relatively high stress load, and from Figs. 4 and 5, it may be advisable to use a higher-quality dataset and map b -values along the faults that have been documented there. Such analyses might have implications for hazards and risk not only for the city of San Juan de Pasto but also for other towns surrounding the volcano.

Summary

The b -value (slope of the frequency-magnitude distribution of earthquakes) around active volcanoes has been mapped at a number of volcanoes around the world and, with information from published sources on types of magmas (Geology data) and pressure conditions inferred for gas exsolution, vesiculation, and mineral stabilization within magma systems (Petrology and Geochemistry data), a possible relation between the depth of b -value anomalies with magma processes is presented. The body of generally accepted knowledge on b -values at volcanoes is summarized and recent data for b -values at Galeras Volcano, Colombia, are analyzed in terms of volcano and earthquake hazards and risk.

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design

Lucia Tirca

Damping; Earthquake; Energy dissipation; Friction dampers; Seismic design; Steel buildings

Introduction

To reduce the seismic demand, researchers have proposed to incorporate supplemental energy dissipation devices into the structural system of buildings. According to the primary dissipation mechanism, supplemental energy dissipation devices are grouped into two categories: hysteretic and viscoelastic. Hysteretic devices rely on the relative displacements of components within the device and are typically based on either metallic yielding or frictional sliding, while viscoelastic devices are velocity dependent. More specifically, friction devices dissipate energy

through the relative sliding developed between two solid interfaces. Depending on the type of friction devices, they could be installed in line with single-diagonal or chevron steel braces, at the intersection of X-bracing system, and in parallel with the beam located at the top of chevron bracing system. The activation of slip forces that characterize the designed friction dampers occur simultaneously with the maximum internal forces allowable to develop in the system during the ground motion excitation. The building reaches the peak interstorey drift when the available slip distance provided by friction damper devices was consumed. “The forces generated by these devices installed in the structural members are usually in phase with the internal forces resulting from ground motion shaking” (Christopoulos and Filiatrault 2006).

The total input energy, E_I , induced by a seismic event into a structural system can be expressed as a summation of kinetic energy, E_k , cumulative strain energy, E_S , inherent damping, E_D , and the hysteretic damping E_h of the seismic force resisting system (SFRS). In this study, E_h is the damping induced by friction devices. The energy balance equation is:

$$E_I = E_k + E_S + E_D + E_h \quad (1)$$

The kinetic and cumulative strain energy are accumulated into the primary structural system and rely on structural damage (Akiyama 2000; Tirca 2009), while the system is damped by both E_D and E_h , which are amplitude-dependent. In general, the contribution of E_D and E_h is related to the amount of post-yielding response and Eq. 1 can be rearranged as follows:

$$E_k + E_S = E_I - (E_D + E_h) \quad (2)$$

In Eq. 1, the term $(E_k + E_S)$ expresses the vibrational energy, E_v , or more specifically the potential damage energy, while $(E_D + E_h)$ is the energy dissipated by viscous damping in the structural members and supplemental devices. Thus, by adding damping into a structural system the elastic vibration energy diminishes, while structural

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design, Fig. 1 Vibrational energy versus supplemental damping

members are protected from damage associated with permanent deformations. In this light, the main design objective is to minimize the difference between the seismic input energy and that dissipated by the dampers (Christopoulos and Filiatrault 2006). The variation of E_v as a function of supplemental damping is depicted in Fig. 1.

Pioneering work on friction devices was conducted by Pall (1979) and Pall and Marsh (1981). Since then, several types of friction dampers have been developed and studied in the literature. These devices differ in their mechanical shape and materials used for the sliding surfaces.

Pall friction dampers dissipate energy through friction developed by the relative sliding within two surfaces in contact which are clamped by posttensioned bolts. In order to obtain stable rectangular hysteresis loops similar to that of Coulomb friction, different types of surface treatment and lining material were studied experimentally. After investigating the response of slip bolted joints under monotonic loading, Pall reported that the most stable behavior was obtained when brake lining pads in contact with mill scale surface on plate was chosen (Fig. 2a). Nevertheless, minor differences between the static and dynamic friction coefficient were observed. However,

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design, Fig. 2 Response of slip-bolted

joint: (a) monotonic test, (b) back-bone curve, and (c) hysteretic behavior (After Pall 1979)

under large seismic excitations, the posttensioned bolts of friction dampers may impact into the end of slotted hole and undergo bearing or even bolt shear failure. The hysteretic behavior of friction damper shown in Fig. 2b is similar to that of an elasto-perfectly plastic system. Herein, the back-bone curve is composed of four segments: elastic, slipping, bearing, and bolt shear failure. When the demand is higher than the available slip length which is equal to the length of slotted hole, a sudden increment in storey shear forces accompanied by decreasing of Coulomb damping is encountered. The hysteresis behavior depicted in Fig. 2c in terms of slip load versus the slip length, Δ , shows rectangular symmetrical loops which are largely influenced by the fluctuation of friction coefficient during the slipping stage. The elastic stiffness, k_o , shown in Fig. 2c, is the stiffness of the attached brace member.

Due to their efficiency (Pall and Pall 2004), Pall friction dampers were employed in more than 40 new and retrofit buildings in Canada,

United States, and India (Christopoulos and Filiatrault 2006). Examples of Pall friction damper installed in an X-bracing system and single-diagonal brace are showed in Fig. 3.

In the last two decades, the following types of friction devices have been developed: slotted bolted connections (Fitzgerald et al. 1989; Grigorian et al. 1993; Tremblay 1993), Sumitomo devices developed by Sumitomo Metal Industries Ltd. of Japan and reported by Aiken and Kelly (1990), energy dissipating restraint damper (EDR) developed by Flour Daniel Inc. (Nims et al. 1993), friction variable damper developed based on the EDR damper (Zhou and Peng 2009), friction damper developed by Mualla (2000), etc.

The energy dissipated by the Sumitomo friction damper is due to friction generated when friction pads, made of cooper alloy with graphite plug inserts, slide directly on the inner surface of the outer cylinder. The precompressed internal spring, incorporated into the device, applies a

F

force that is converted through the action of inner and outer wedges into a normal force on the friction pads. Sumitomo device can be installed in parallel to the beam located on top of chevron bracing system or in-line with steel braces. As reported by Aiken and Kelly (1990), Sumitomo dampers were used in two high-rise buildings in Japan in order to resist small intensity earthquakes and ground floor vibrations.

The EDR damper is similar to Sumitomo device. It includes the following components: an internal spring, steel compression wedges, bronze friction wedges, stops at both spring's ends, and the outer steel cylinder. Its functioning comprising the generating slip force depends on the length of the internal spring. In addition, the normal force acting on the cylinder wall and the friction force developed between the bronze friction wedges and the inner surface of the outer cylinder determine the slip force in the device. As noted by Nims et al. (1993), the EDR device can produce a wide range of hysteretic behavior such as double-flag shape and triangular lobed shape. Both types of hysteresis loops are self-centering. By using the same principles, Zhou and Peng (2009) proposed a new friction variable damper where a sliding shaft and a friction ring were used to replace the spring and wedges. In addition, two zones with high and low friction coefficient have been defined in the internal walls of the outer cylinder.

The friction damper proposed by Mualla (2000) was added to connect the top part of chevron braces to the mid-span of a moment resisting frame beam. This friction damper, patented by DAMPTECH Denmark, consists of three steel plates that are able to rotate against each other around a pre-stressed bolt which passes through. Two circular friction pad discs inserted between the aforementioned steel plates provide dry friction lubrication and ensure stable friction forces. As reported by Liao et al. (2004), a full scale test conducted on a three-storey moment resisting frame with added chevron bracing system and Mualla's dampers was investigated. The total weight of the frame was about 34 t. The bracing system consisted of bar members that were pre-tensioned in order to avoid buckling. Due to the application of lower scaling simulated ground motions, no damage of structural members was reported during the conducted experimental tests.

Design Provisions

Since 1980, seismic response control techniques have been used as complementary solutions to the existing SFRSs. Despite of their wide-spread applications, design guidelines for structures equipped with supplemental energy dissipation devices (hysteretic and viscoelastic) are still in evolving phases. This study refers to the design

philosophy of structures with incorporated friction damper devices (FDD). As mentioned above, FDDs are hysteretic devices. For example, buckling-restrained braces are also known as hysteretic damper devices and are designed to dissipate part of vibration energy through yielding of the core plate.

In general, hysteretic devices are installed in braces and are able to undergo large inelastic response, while they dissipate most of the hysteretic energy. The purpose of installing these devices into the structural system is to maintain the main structure either elastic or within low inelastic deformations. Both, the main frame and the supplemental energy dissipation system, share the same deformation, which in turn is that of the entire system. It is important to assure stable response of these devices under dynamic loading. Thus, the added dampers installed in new or retrofit buildings should yield or slip before the shear resistance of the main structure is reached.

In North America, the first design guidelines addressing provisions for passive energy dissipated devices were introduced in FEMA 356 (2000) and FEMA 450 (2003) that refer to the seismic rehabilitation of buildings and seismic design for new buildings, respectively. Later on, FEMA 450 was replaced by FEMA-P 750 (2009). The aforementioned design guidelines were incorporated in Chapter 14 of ASCE/SEI 41-13 (Seismic evaluation and retrofit of existing buildings), as well as in Chapter 18 of ASCE/SEI 7-10 standard. It is noted that *Commentary J* of NBCC 2010 (National Building Code of Canada) includes two clauses in regard to seismic design with supplemental energy dissipated devices. However, both CSA/S16-2009 and ANSI/AISC 360-2010 standard provide design regulations for the “ductile buckling-restrained braced frames” system.

In Europe, the Eurocode 8 part 1 (CEN 2004) contains Chapter 10 entitled *Base isolation*, but this chapter does not cover regulations for passive energy dissipation devices installed into several storeys of building’s structure.

The aforementioned guidelines specify general requirements, analysis procedures, required

testing program, etc. A brief review of these guidelines with highlights on friction damper devices design is presented below.

FEMA P-750 and ASCE/SEI 7-10 Provisions

Design Philosophy

General requirements:

- Structures with a damping system have a seismic force resisting system that provides a complete load path. The base shear used to design the employed SFRS shall not be less than $V_{\min}$, where $V_{\min}$ is the greater of:

$$V_{\min} = V/B_{v+1} \text{ and } V_{\min} = 0.75 V.$$

Herein, V is the seismic base shear in the direction of calculation determined in accordance with the code procedure corresponding to the selected SFRS and B_{v+1} is the numerical coefficient set for effective damping reduction factor that is equal to the damping provided by supplemental dampers in addition to the inherent damping (2 % for steel structures). For irregular building structures and for damping system that has less than four damper devices per floor disposed in the direction of loading, the minimum base shear will not be less than $1.0 V$.

- Damping system may be used in addition to the SFRS in order to meet interstorey drift limits and it may be located external or internal to the structure, while it shares or not the members of SFRS. In Fig. 4 is illustrated a SFRS consisting of one bay moment resisting frame (MRF) and a damping system composed of diagonal braces with installed FDs. The FD system is located independently to the MRF system.
- Energy dissipating devices must be tested before installation for displacement and slip force corresponding to seismic demand that is required by code.
- Linear static and response spectrum analysis methods for design are accepted for regular

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design,
Fig. 4 Configuration of SFRS and damping system (no shared elements)

structures that have at least four damper devices per each floor located in one principal direction of the building. Like MRF or braced frame structures, damped structures yield during the design ground motions, while they need to behave elastically under the wind loads.

- For detailed design and seismic response investigations, nonlinear dynamic time-history analyses are recommended.
- Dampers are modeled to perform in the plastic range. The computer model should be calibrated based on experimental test results. For designs in which the SFRS is expected to yield, the postyield behavior of the structural elements must be modeled explicitly.

In the ASCE/SEI 7-10 provisions, damping system is defined as being “the collection of structural elements that includes all the individual damping devices, all structural elements or bracing required to transfer forces from damping devices to the base of the structure, and the structural elements required to transfer forces from damping devices to the seismic force-resisting system.” For details of design procedure, the reader is referred to the ASCE/SEI 7-10 document. It is noted that other design methodologies can be applied to design structures equipped with friction dampers.

Design of Structures Equipped With Pall Friction Dampers

As noted above, metallic dampers and friction dampers are hysteretic dampers. The design of structures equipped with metallic dampers or friction dampers is similar. The difference

consists of changing the yield load corresponding to metallic dampers with the slip load of friction dampers. As mentioned above, friction dampers are installed in braces and are designed not to slip under the wind forces. On the other hand, in order to increase the building performance under earthquake loads, systems composed of friction-damped braces are added to the MRF structures, while the MRF system should possess enough strength, stiffness, and ductility. Furthermore, all members of the SFRS and those attached to FDs should be designed to carry the internal forces developed when slip forces are activated. Thus, the application of capacity design checks to structural members is required. According to Christopoulos and Filiatrault (2006) the design of structures equipped with friction dampers can be divided in four steps:

- Calculate the demanded slip force and size the in-line brace by employing simplified methods (e.g., the equivalent static force procedure). Then, the demanded peak interstorey drift (e.g. linear dynamic analysis methods) should be evaluated.
- Optimize the design of friction dampers and adjacent members.
- Apply the capacity design and size all structural members to carry the designed slip forces.
- Use the nonlinear time-history dynamic analysis to check the design performance of building structure under an ensemble of selected ground motions scaled to match the design response spectrum corresponding to 2 % probability of exceedance in 50 years (NBCC 2010).

A review of different design procedures from the literature is discussed below. However, in all design procedures, the building structure is composed of a bare frame system and a supplemental damping system, whilst its response is analyzed before and after the friction dampers are activated.

Design Procedures from the Literature

The first design procedure for MRF system equipped with friction damped braces was proposed by Baktash and Marsh (1986). They considered a single storey MRF structure with friction damped braced bays. Based on this procedure, the slip force is activated when yielding in the moment resisting frame brace is reached. For a single bay MRF frame that was designed based on the principle “strong column weak beam”, the shear force resisted by the frame action, V_s is related to the plastic moment capacity of the MRF beam, M_p . Herein, $M_p = V_s h/2$, where h is the storey height. Thus, the proposed design method is based on the assumption that the lateral shear force leading the damper in-line with brace to slip must be equal to the shear force causing the MRF to yield and is expressed by the following equation:

$$V_s = 2M_p/h \quad (3)$$

The corresponding shear deflection of the storey, Δ_s is:

$$\Delta_s = (V_t - V_{br})/k_u \quad (4)$$

where V_t is the total shear force exerted by the frame and braces, V_{br} is the total shear force exerted by braces alone, and k_u is the lateral stiffness of the bare MRF.

The hysteretic energy dissipated by friction devices E_f is:

$$E_f = V_{br}\Delta_s = V_{br}(V_t - V_{br})/k_u \quad (5)$$

By differentiating Eq. 5 with respect to V_{br} and setting it equal to zero, the maximum energy dissipated by friction devices is obtained:

$$\delta E_f / \delta V_{br} = V_t/k_u - 2V_{br}/k_u = 0 \quad (6)$$

From Eq. 6, the shear force exerted by braces is:

$$V_{br} = 0.5V_t \quad (7)$$

Thus, to maximize the energy dissipated by friction devices, the total shear force must be equally shared between friction devices and the bare frame (MRF). In addition, it was reported that the optimum slip force of friction devices installed in structure depends on the structural characteristics only and not on the ground motion intensity (Baktash and Marsh 1987).

Filiatrault and Cherry (1988) proposed to determine the optimum activation of friction devices based on minimizing the *Relative Performance Index*, RPI, devised from the application of the energy concept.

$$RPI = \frac{1}{2}[SEA/SEA_0 + U_{\max}/U_{\max 0}] \quad (8)$$

where SEA is the strain energy area of all structural members of a friction damped system, SEA_0 is the strain energy area corresponding to a zero activation force, $U_{\max}$ is the maximum strain energy stored in all structural members of a friction damped system, and $U_{\max 0}$ is the maximum strain energy for a zero slip force. The values resulted for the RPI yield to three cases: (i) $RPI = 1$ corresponds to the response of a bare frame structure; (ii) $RPI < 1$ corresponds to the response of a damped structure which is smaller than the response of the bare frame structure; (iii) $RPI > 1$ corresponds to the response of a damped structure which is larger than the response of the bare frame structure. Authors recommended the selection of diagonal braces to comply to $T_b/T_u < 0.4$, where T_b and T_u are the fundamental period of the braced frame structure and bare frame structure, respectively. Herein, the fundamental periods T_b and T_u can be expressed as $T_b = 2\pi/\omega_b$ and $T_u = 2\pi/\omega_u$, where ω_b is the natural circular frequency of the fully braced frame before dampers are activated, $\omega_b = (k_b/m)^{0.5}$ and ω_u is the natural circular frequency of bare frame, $\omega_u = (k_u/m)^{0.5}$. In addition, k_b and k_u are the lateral stiffness of the

braced frame structure and bare frame structure, respectively. In these expressions, m is the total seismic mass of the system. Later on, Filiatrault and Cherry (1990) proposed the following equation to calculate the total shear force, V_o that is required to activate all friction damper devices in a structure:

$$V_o/W = (a_g/g) \times Q(T_b/T_g, T_b/T_u, N_f) \quad (9)$$

where N_f is the number of floors, a_g is the design peak ground acceleration, g is the gravity acceleration, T_g is the predominant period of the selected design ground motion, and Q is an unknown single valued function that is given in Eq. 10a for $0 \leq T_g/T_u \leq 1$ and Eq. 10b for $T_g/T_u > 1$.

$$Q = (T_g/T_u) \times [(-1.24N_f - 0.31)T_b/T_u + 1.04N_f + 0.43] \quad (10a)$$

$$Q = (T_b/T_u) \times [(0.01N_f + 0.02)T_g/T_u - 1.25N_f - 0.32] + (T_g/T_u) \times (0.002 - 0.002N_f) + 1.04N_f + 0.42 \quad (10b)$$

Equations 9 and 10a or 10b can be used directly to calculate the total base shear force V_o . It is noted that for a single diagonal brace located at floor i , the slip force is P_i and the activation shear at that floor is $V_i = P_i \cos\theta_i$, where θ_i is the angle of brace inclination reported to a horizontal line.

In the meantime, studies on hysteretic bracing systems were carried out by Ciampi et al. (1990, 1992, 1995, etc.) who considered that both MRF and bracing system are arranged in parallel. They concluded that the activation of friction damper devices should occur before yielding of moment resisting frame. In addition, Ciampi et al. (1995) referred to four key parameters such as:

- T_f , which is the fundamental period of the bare moment resisting frame. A deductible parameter is $\alpha = T_b/T_f$ where T_b is the fundamental period of the bracing system.

- $\lambda = k_b/k_f$ which is the ratio between the stiffness of bracing system and the stiffness of the bare moment resisting frame.
- $\beta = \delta_{by}/\delta_{fy}$ which is the ratio between the displacement that cause yielding of bracing system and that that causes yielding of bare MRF system.
- $\eta_f = F_{fy}/ma_g$ which is the yield strength of the frame normalized to the mass of the structure multiplied by the design peak ground acceleration. Similarly, it can be defined $\eta_b = F_{by}/ma_g$, where F_{by} is the yield force of bracing system. The total normalized force is $\eta_{II} = \eta_f + \eta_b$.

The selection of the above parameters suggests the variation effect of β and λ on the building response. When $\beta = 1$, bracing system and MRF system yield for the same lateral displacement. When $\beta = 0$, the structural system corresponds to the MRF system only. They recommended an optimal value of β around 0.5.

The application of this design methodology to MDOF systems requires uniform distribution of stiffness and slip forces along the building height, aiming at uniform activation of friction devices in order to avoid damage concentration within a specific floor. In addition, they proposed to maintain at each storey the stiffness of braces proportional to the bare frame stiffness. Also, they recommended keeping proportionality between the horizontal projection of slip forces per floor and the corresponding static or dynamic distributed storey shear over the building height. In addition, two design assumptions were made: (i) the MRF system is designed to respond elastically while the friction damper devices behave in the non-linear range and (ii) the MRF system may yield when δ_{fy} was reached, therefore after friction damper devices were activated. The tri-linear force-displacement constitutive law is depicted in Fig. 5.

Fu and Cherry (1999, 2000) proposed a simplified design method that leads to a code compatible procedure for a *friction-damped steel braced frame system*. First, they developed the method for a SDOF system based on establishing an equivalent ductility-related force modification

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design, Fig. 5 Trilinear force-displacement constitutive law (After Ciampi et al. 1995)

factor R , which reflects the capacity of the system to dissipate energy. They have developed a trilinear model similar with that illustrated in Fig. 5, where η parameter was replaced by the restoring force of a SDOF system, $f(t)$. In addition, η_l and η_{III} parameters were replaced by f_s and f_y , where f_s is the slip restoring force (after dampers were activated) and f_y is the yielding restoring force developed when $f(t)$ exceeds f_y and the frame members yield. Thus, to design the friction-damped steel braced frame system, the design base shear is first calculated based on the code procedure (e.g. equivalent static force procedure). In this case, the value assigned to the R factor (R_d in the current NBCC code) is evaluated based on the selected system parameters. Then, all members are designed based on forces resulted from the distribution of design base shear over the building height, and the brace stiffness and slip forces are evaluated at each floor. In this study, friction-damped braces were installed in a ductile steel MRF system. The response of building designed based on the employed R factor should be verified such that the demanded lateral frame deflection under the wind and earthquake load to be maintained below the code limits. For example, according to the NBCC 2010 requirements, the system must respond elastically under the wind load, while the interstorey drift should

not exceed $h_s/500$. Under earthquake loads, the maximum interstorey drift should be less than $2.5\%h_s$ for a building classed under the normal category. Herein, h_s is the storey's height.

Tirca (2009) proposed a design methodology to upgrade the seismic resistance of an existing steel moment frame building designed before 1970. The method complies with FEMA 356 (2000) provisions. First, the available elastic base shear, V_f , provided by the existing steel moment frame system was evaluated by using modal response spectrum method and a three-dimensional building model. Then, the required base shear carried by friction-damped braces V_{br} was computed as being the difference between the code demand, V , and V_f . Herein, V is the minimum lateral earthquake force computed based on NBCC provisions by setting $R_d = 1.0$. The effect of torsion was included. By considering the nonlinear behavior of friction dampers, the resulted base shear assigned to friction-damped braces, V_{br} was divided by B_{v+l} as per FEMA 356 and then was distributed over the structure height. According to FEMA 356 recommendation, minimum four friction-damped braces displaced in the direction of loading were installed in each floor. The slip force of each device located at storey i was computed by divided the corresponding storey shear force resulted from a dynamic analysis to the number of friction-damped braces and to the $\cos\theta_i$, where θ_i was defined above. All steel braces were designed to behave elastically while sustaining the nonlinear response of attached friction damper. Thus, braces were sized such that $130\% C_r$ to be larger than the slip force, whereas C_r is the brace compressive resistance. To preserve the existing columns of MRF system in elastic range, it was proposed to stagger the installation of friction-damped braces such that to minimize torsion. To prevent the concentration of damage at specific storeys, it was proposed to maintain a constant ratio between the horizontal projection of slip forces and dynamic distributed storey shear over the building height. However, the available slip length should be recommended in the design phase in order to avoid sudden failure. The displacement at yield, Δ_y , depends on the

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design, Fig. 6 Mechanical model of a SDOF system

stiffness of friction-damped braces, k_{bd} , as shown in Fig. 2c. As noted above, the stiffness of the frame and the stiffness of friction-damped braces are in parallel ($k_f + k_{bd}$), whereas $\Delta_y = F_s/(k_f + k_{bd})$ and F_s is the slip restoring force. In this study, the seismic response of retrofitted building equipped with friction-damped braces was verified to remain within the interstorey drift code limits and forces developed in structural members to be below the members' resistance. It was concluded that friction-damped braces installed in moment frame buildings are able to control the interstorey drift and floor acceleration.

Numerical Modeling of Friction-Damped Braces

In general, researchers select the bilinear force-deformation model for simulating the behavior of friction damper devices. When performing nonlinear time-history analyses, convergence problems may arise due to the sharp transitions from the elastic to inelastic stages during the loading, unloading, and reloading cycles. Due to the large number of friction devices installed in a building structure, the bilinear model "can become computationally inefficient" when these devices are in different phases of stiffness transition (Moreschi and Singh 2003). To overpass this modeling drawback, the Bouc-Wen model is recommended. In addition, in the case of Bouc-Wen model, it is the same differential equation that governs its response (Eq. 11) and more specifically its behavior during different transition stages. Therefore, the Bouc-Wen model is able to

simulate the highly nonlinear Coulomb friction and has the ability to represent different hysteresis shapes according to the values of the parameters involved (Morales Ramirez 2011). Since the desired shape of the Coulomb dry friction law is symmetric and strength and stiffness degradation is neglected, the Bouc-Wen model is reduced to a nonlinear restoring force (Eq. 11) of a SDOF system shown in Fig. 6. The evolutionary variable z , given in Eq. 11, is defined in Eq. 12.

$$f_s(\dot{u}, z) = \alpha k_o u + (1 - \alpha) k_o z \quad (11)$$

$$\dot{z} = \dot{u} \left\{ \frac{A - |z|^n [\gamma + \beta \text{sgn}(\dot{u}z)] v}{\eta} \right\} \quad (12)$$

In the above equations, α is the participation ratio of the initial stiffness in the nonlinear response, k_o is the initial stiffness of the system, u is the displacement of the SDOF system, and z is the hysteresis variable. In Eq. 12, γ and β are parameters controlling the shape of the hysteresis cycle and the exponent n influences the sharpness of the model in the transition zones. The remaining parameters A , v , and η control the degradation process in stiffness and strength. When the degradation process is neglected, the aforementioned parameters are $A = A_o$, $v = 1$, and $\eta = 1$. The considered SDOF system is characterized by the restoring force $f_s(du/dt, z)$ that has a linear and a nonlinear component, as defined in Eq. 11. Using $n = 1$ might yield to a flexible behavior, while increasing the period of vibration and reducing the inertial forces. The smooth transition toward a rectangular hysteresis shape is obtained for a large value of variable n which might become computationally expensive, because the transient

Friction Dampers for Seismic Protections of Steel Buildings Subjected to Earthquakes: Emphasis on Structural Design, Fig. 7 Friction-damped brace: (a) Schematic model and (b) Hysteresis model plus the bearing state

analysis requires the calculation of the evolutionary variable z at each step of time for a single element. By using $n = 10$, it gives an acceptable level of prediction because the difference is quickly reduced throughout the evolution of the slipping stage.

To simulate the slip and slip-lock phases of friction-damped brace device in OpenSees (McKenna and Fenves 2004), Morales Ramirez (2011) proposed a novel equivalent uniaxial material composed of BoucWen material (BW) in parallel with gap springs made of Elastic-Perfectly Plastic Gap material (EPPGap), which are already available in the OpenSees library (Mazzoni et al. 2006). The friction damper was arranged in series with the brace member made of steel material. The brace was modeled with a truss element. The schematic representation of friction-damped brace device is shown in Fig. 7a. In the illustrated model, BoucWen material was selected to replicate the smooth hysteresis behavior of friction damper (stick-slip and slip phase), which was activated when the axial stress σ_s generated by the slip force P_s was reached ($\sigma_s = P_s/A_{br}$ and A_{br} is the gross area of the attached brace). Each friction damper is characterized by its slip force and slip length that are resulted from calculation. However, under strong ground motions, the provided slip length, u_a , may be limited and the pretensioned edge bolt may drive the friction damper into the slip-lock phase as depicted in

Fig. 7b (Morales Ramirez and Tirca 2012). Herein, u_y is the elastic axial deformation of the brace. To simulate the slip-lock phase, one equivalent EPPGap spring made of three bilinear gap springs arranged in parallel each other are defined to act in tension and another set in compression. Each uniaxial *ElasticPPGap* material (OpenSees notation) has a defined stress-strain or force-deformation relationship either in tension or in compression. Thus, one equivalent EPPGap spring is activated when the displacement demand exceeds the available slip length, $+u_a$, and the other is activated when the $-u_a$ slip length is reached. Once activated, this component is able to limit the displacement and to increase the force experienced by the friction damper. The threshold force of these gap elements is related to the maximum force that the device is able to withstand ($P_s + f_d$) without reaching failure (Fig. 7b). To control the failure phase, the *MinMax* material was set to decouple the friction device when the strain of the *ElasticPPGap* material exceeds the predefined bounds either in tension or compression. In addition, when the *MinMax* material is activated (e.g., $t = t_i$), the device is decoupled from $t = t_i$ until the end of analysis.

Detailed design examples of 4-, 8-, and 12-storey MRF building equipped with Pall friction dampers installed in-line with braces are given in Morales Ramirez (2011) reference. The building is located in Montreal, Canada, and was subjected to ten simulated and historical ground

motions scaled to match the design response spectrum over the period of interest $0.2 T_1$ – $1.5 T_1$, where T_1 is the fundamental period of the building. All analyses were performed using OpenSees.

To evaluate the seismic response of structures equipped with friction-damped braces, the following parameters should be investigated: interstorey drift, lateral deflection, and residual interstorey drift.

For an accurate OpenSees model of friction-damped brace, it is required to calibrate the model against experimental test results. Presently, experimental tests conducted on Pall friction dampers installed in-line with braces are carried out and the obtained results will be disseminated. Furthermore, the development of a code-based design method for structures equipped with friction-damped braces is required.

Summary

Since 1980, seismic response control techniques have been used as complementary solutions to the existing seismic force resisting systems and several types of friction damper devices were developed. Among them, Pall friction damper devices are the most popular. However, despite of their wide-spread applications, design guidelines for structures equipped with supplemental energy dissipation devices are still in an evolving phase. This study refers to the design philosophy of structures with incorporated friction dampers that in most cases are installed in-line with steel braces. A brief review of design guidelines and other seismic design provisions that emphasize on the design of friction-damped braces is presented. In addition, a brief discussion on the numerical modeling of friction-damped braces was conducted.

Geotechnical Earthquake Engineering: Damage Mechanism Observed

Damage; Deformation; Earthquake; Fault; Liquefaction; Shaking

Introduction

In the modern community, there are a variety of problems caused by earthquakes, including such traditional ones as collapse of buildings and slope failures as well as lifeline problems and economic damages which became important in the recent times. Thus, new types of problem have been recognized as our culture and civilization change with time. It is also important to know that the safety demand is rising continuously with time.

Earthquake engineering addresses a large number of issues that are related with the past experiences of damage, their causative mechanisms and mitigations. Because of the complexity of the problem, the issues to be discussed range widely from geological and mechanical topics to

societal and legal issues. It is obviously impossible for one author to deal with everything. The present author was requested to write general remarks on geotechnical issues and there are many things to be picked up. Because of the page limitation and expectation that other authors will write more about technical issues, it was decided that this entry should address geotechnical damages so far experienced and their causative mechanisms with some suggestions on future directions. Because the human civilization is changing continuously, it cannot be stressed too much that more new problems will occur at any time and that all the readers of this encyclopedia make efforts to develop new solutions. To achieve this goal, it is important to visit the real earthquake damage sites and draw lessons from these real case studies.

Damage Caused by Ground Shaking

Intensity of Seismic Motion and Subsoil Conditions

Collapse of houses has been and still is the most important kind of seismic damage. Figure 1 illustrates a building crash. While this building was subjected to a complicated effect of ground shaking, it is generally agreed that the horizontal shaking is more responsible for the damage than the vertical component. The reason for this is that any structure has a safety margin under the gravitational action, and the vertical seismic action is

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 1 Seismic collapse of RC building (2001 Gujarat earthquake of $M_w = 7.7$ in India)

resisted to a reasonable extent by this margin, whereas there is no significant safety margin against the horizontal action produced by earthquake excitations. Consequently, many efforts have been made in the recent times to improve horizontal resistance in structures.

It has been widely recognized that earthquake damage is more substantial upon soft soil deposits than on firm soil or rock outcrop. This belief is supported by an experience during the 1923 Kanto earthquake of $M_w = 7.9$ in Tokyo. Figure 2a illustrates the geomorphology of the present Tokyo at the end of the sixteenth century when the urban development was started. The eastern part of the area used to be a mouth of a big river surrounded by swamps and rice paddies underlain by soft and loose soils. In contrast, the western part of the area is composed of higher terraces covered by volcanic ash materials, associated with occasional small valleys that were produced by erosion and filled with soft soils. Figure 2b illustrates the distribution of earthquake damage percentage of traditional wooden houses. Note that this damage implies the damage by shaking and does not include those by big fires that finally destroyed most parts of the city. In this figure, a good consistency can be found between the distribution of soft soils in the eastern part and in valleys and the location of high damage rate.

Amplification of Ground Motion in Soft Soil

The intensity of ground motion is increased by the surface soft soil deposits and this phenomenon is called amplification. It is known that the extent of amplification changes basically with the thickness of the surface soil (H) and the velocity of S-wave propagation (V_s). The S(econdary)-wave means a propagation of shear deformation and the theory of elasticity defines its velocity by

$$V_s = \sqrt{\frac{G}{\rho}} \quad (1)$$

in which G and ρ stand for the shear modulus and mass density of soil, respectively. More precisely, the extent of amplification is a function of $2\pi fH/V_s$ where f designates the number of shaking cycles per second (frequency). The most significant amplification, which is called resonance in subsoil, occurs when $2\pi fH/V_s = \pi/2$, and therefore the frequency is equal to $V_s/(4H)$. This implies that the surface ground motion is dominated by a component of this special “resonant” frequency although the motion in the base rock at a deep elevation includes many frequency components in a random manner.

Resonance occurs also in structures upon the ground surface. Generally, soft wooden houses with heavy roofs have low resonant frequency.

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 2 Correlation between subsoil conditions and earthquake damage of wooden houses in Tokyo during the 1923 Kanto earthquake

(Drawn after Murai 1994). (a) Original geomorphology of Tokyo (Drawn after Murai 1994). (b) Distribution of house damage in 1923 (Okamoto 1973)

Therefore, if the surface ground motion is rich with (dominated by) low-frequency components, the seismic response of such house is significant and heavy damage is likely. In contrast, rigid structures have higher resonant frequencies and are prone to damage if located upon stiff soil where H is small, V_s is high, and $V_s/(4H)$ is close to the structure's resonant frequency. Figure 3a, b illustrates two wooden houses, one crushed house on soft alluvium and survival of the other on a firm gravelly fun deposit. On the contrary, Fig. 3c shows a rigid warehouse that was located on a firm gravelly fun and suffered a significant damage during the earthquake.

Seismic Inertial Force

The earthquake resistant design in the modern times was established by the use of seismic inertial force. Theoretically, this force is related with the maximum acceleration (PGA) by

Seismic inertial force for design
= (Weight of structure) $\times$ PGA/g (2)

where g stands for the gravitational acceleration ($=9.8 \text{ m/s}^2$) and PGA is affected by the aforementioned amplification of motion. Noteworthy is that this inertial force is considered to be a static force that lasts permanently despite that the real earthquake action occurs for a much shorter time. Hence, Eq. 2 overestimates the real seismic effect. To compensate for this, PGA in Eq. 2 has to be made smaller than the real maximum acceleration.

Equation 2 implies that the maximum acceleration or its equivalent inertial force controls the seismic failure of structures. This type of failure is the case of a brittle structure which collapses if the external load exceeds the resistance; see Fig. 4. Because traditional masonry buildings and wooden houses were of brittle nature, seismic design by means of this static seismic design

**Geotechnical

Ductile and brittle behaviors of structure

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 4 Schematic illustration of ductile and brittle behaviors

force achieved significant success in the first half of the twentieth century. Noteworthy is that the second half of the century developed ductile structures (Fig. 4) of which seismic deformation plays major roles in their seismic performance-based design. Moreover, underground lifelines are more affected by ground deformation than the inertial force. Therefore, *PGA* is not so important today, and the maximum velocity (*PGV*), response spectrum, duration time of shaking, and the number of loading cycles are often referred to in seismic risk assessment. Note that Mexico City experienced significantly intensified ground motion and elongated duration time of shaking due to its basin structure and soft soil deposits during the 1985 earthquake of $M_w = 8.3$.

Seismic Soil-Structure Interaction

Structures in contact with soil are always subject to the soil-structure interaction. Mononobe-Okabe theory of seismic earth pressure (Mononobe and Matsuo 1929; Okabe 1924) addresses the interaction of a rigid retaining wall and backfill soil which has yielded during shaking and exerts pressure on a wall. Note that the theory hypothesized that the wall has translated substantially to produce the active earth pressure in the backfill. Thus, the Mononobe-Okabe earth pressure is not the pressure during earthquakes but the active pressure after large deformation. Because of the long history of

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 5 Failure of retaining wall due to significant seismic earth pressure from backfill soil (near Hanshin Ishiyagawa Station during the 1995 Kobe earthquake; $M_{jma} = 7.3$)

practice, the Mononobe-Okabe theory has successfully reduced the number of failure of retaining walls. An exceptional case is shown in Fig. 5. More recent experiences suggest that attention should be paid to the foundation of a retaining wall. For example, Fig. 6 shows a case in which a concrete wall resting on unstable fill failed and translated substantially.

Pile foundation is subject to soil-structure interaction during earthquakes as well. As illustrated in Fig. 7, piles are first subjected to the horizontal seismic load that occurs in the superstructure (inertial effect). Second, piles are affected by the differential movement between pile and soil (kinematic pile-soil interaction). In case that soil is very soft, soil translates more than piles and hence piles are loaded in the same direction as the seismic force in the superstructure (Fig. 7a). It seems that such a difficult situation was hardly considered in the past; soil was supposed to be stable and resisted against the pile deformation (Fig. 7b). When the horizontal capacity of pile foundation is not sufficient, one

Geotechnical Earthquake Engineering: Damage Mechanism Observed,

Fig. 6 Translation of retaining wall triggered by failure of unstable fill in its foundation (in Takamachi residential area, Nagaoka, during the 2004 Niigata-Chuetsu earthquake of $M_w = 6.6$)

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 7 Schematic illustration of pile-soil interaction during earthquakes. (a) Soil displacement > pile displacement. (b) Soil displacement < pile displacement

mitigation is to enlarge the size of foundation and increase the number of piles (Fig. 8).

Underground Structure and Earthquake Motion

The deformability of subsoil as illustrated in Fig. 7a is important because this is one of the main reasons why underground structures are destroyed during strong earthquakes. Figure 9 illustrates depression of ground surface that was caused by the collapse of a metro station in Kobe in 1995. This station collapsed because the surrounding backfill soil was not sufficiently firm

and exerted load on the station. Central columns in the station were destroyed, the ceiling fell down, and the ground surface caved in. Noteworthy is that soil becomes softer during strong shaking because shear strain in soil during strong shaking is greater and shear modulus of soil decreases as shear strain amplitude increases. Such a situation was not fully considered in the past when subsoil was optimistically assumed to reduce the deformation of underground structures. After this lesson was learned, central columns in many subway stations were reinforced to avoid future problems (Fig. 10). However, the

Geotechnical Earthquake Engineering: Damage Mechanism Observed,

Fig. 8 Increasing the number of piles to resist stronger earthquake force (Kobe)

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 9 Depression at ground surface above the collapsed subway station (Kobe 1995, Photo by Prof. Nozomu Yoshida)

success of reinforcement depends on the intensity of earthquake shaking during future earthquakes.

Similar situation is found in the significant deformation of a tunnel in “soft” rock (Fig. 11).

Note that tunnels used to be considered stable during earthquakes because surrounding “hard” rock was expected to reduce the deformation of tunnel during earthquakes.

Geotechnical Earthquake Engineering: Damage Mechanism Observed,

Slope Instability

Gigantic Failure of Slopes

In addition to collapse of houses, slope failure caused by earthquake shaking is another traditional and important type of seismic disaster. If its size is huge, slope failure may kill thousands of people. For example, the failure of the slope of Mt. Huascarán in Peru triggered by the 1970 Ancash earthquake of $M_w = 7.9$ caused a huge avalanche flow that overtopped a natural protection hill, buried Yungay City (Fig. 12), and

instantaneously killed 20,000 residents (Plafker et al. 1971). After this tragedy, Yungay moved to a safer place.

The 1964 Alaska earthquake of $M_w = 9.2$ caused a submarine landslide in the Port of Valdez. The abrupt and significant change of the submarine topography triggered a huge tsunami that washed the Valdez township and claimed more than 30 lives. Figure 13 shows an aerial view of the site of former Valdez. It seems that the failed submarine slope consisted of fine nonplastic sediments that were transported

from the glacier through the river in the figure into the sea bottom. The fine grain size of the material made the sedimentation rate very low in the seawater, resulting in loose deposit, while the lack of cohesion made the material highly prone to liquefaction. Even worse was that the fine grain size reduced the permeability and hence the dissipation of excess pore water pressure during shaking was very slow.

Consequently, this submarine slope easily liquefied and failed during the gigantic earthquake and triggered a tsunami.

Natural Dam

The 1999 Chi-Chi earthquake in Taiwan registered $M_w = 7.7$. The rock mass in the geologically young Taiwan island was not fully lithified. The complicated tectonic environment around

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 14 Tsao-Ling slope failure in Taiwan caused by the 1999 Chi-Chi earthquake

the Taiwan island disturbed the rock mass. The high extent of annual rainfall made steep slopes in the mountainous regions. These situations were combined to develop many slope failures during the earthquake. Among them the biggest slope failure occurred in Tsao-Ling (Fig. 14), and 120 million m^3 of materials flowed down into the river to form a natural dam (Hung 2000). This slope had failed several times in the past because of heavy rains or earthquakes in 1862, 1941, 1942, 1979, and 1999 (Hung 2000). Noteworthy was that the 1999 event produced a big natural dam, similar to the previous event in 1941 (Kawata 1943), and a reservoir which was later filled with river sediments.

The 2008 Wenchuan earthquake of $M_w = 7.9$ in the Sichuan Province of China affected mountainous area where body of mountains has been deteriorated by the tectonic action. Slope failures produced natural dams (Fig. 15). The problem of the natural dams is the possibility of breaching and flooding in the downstream area. Therefore, it is important after big earthquakes in mountain regions to find the formation of natural dams and if a dam is subject to overtopping, erosion, and breaching to drain water as soon as possible. Empirically it is known that seepage and piping failure is rather rare in natural dams (Tabata et al. 2002).

The travel distance of a failed landslide mass (runoff distance) is an important issue because the longer runoff results in damage in a bigger area. Hsü (1975) proposed to study the H/L ratio of the soil flow geometry in which H stands for the height of fall of the soil mass, while L the horizontal travel distance, H/L suggesting $\tan$ (friction angle) where the friction angle is in terms of the total stress. Figure 16 was drawn by collecting data from many literatures. It is important herein, as has been pointed out by many authors, that the greater volume of soil mass is associated with the smaller H/L and, hence, the friction angle. Submarine slope failures are accompanied by even smaller friction angle.

Instability of Slope Surface

It is often the case that a mountain slope is covered by a weathered unstable material. This weak surface material may fall down during strong shaking. Although the size is small, this type of slope failure occurs at many places and often close mountain roads, making emergency activities very difficult.

Figure 17 reveals a typical seismic failure of a mountain slope. While rainfall-induced slope failures often start from the shoulder of a slope, earthquake-induced failures start from the mountaintop. It should be stressed that slopes of

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 15 Site of natural dam of Qing zhu Jiang River near Qingchuan, Sichuan Province, China

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 16 Empirical relationship between height of fall (H) and horizontal travel distance (L) of landslide mass (Reproduced from p. 309 of Towhata (2008))

volcanoes are more vulnerable to failure because, first, generally the volcanic slopes are made of ashes and pumices without rigid rock mass and, second, these materials are pervious and include a big amount of water. The volcanic slope in Fig. 18 started its failure from the top.

Another problem of slope instability has emerged in residential land developments in hilly areas where cut and fill is a common way of construction. Being different from public and industrial projects, individuals cannot always afford reliable but expensive safety measures. As a business practice, therefore, residential

lands have been constructed in a less costly manner. As a consequence, unfortunately, fill parts of land became unstable during strong earthquakes. See Fig. 19. Because residents do not have engineering knowledge, quality assessment of residential lands is recommended as an urgent necessity.

Long-Term Effects of Earthquake Shaking on Slope Instability

It is noteworthy that strong earthquake shaking in mountainous regions may initiate long-term instability of slopes and debris-flow hazards.

**Geotechnical
Earthquake Engineering:

**Geotechnical
Earthquake Engineering:
Damage Mechanism
Observed,**

Fig. 18 Failure of slope of volcanic deposits, Costa Rica, 2008, after the Cinchona earthquake of $M_w = 6.1$

The slope in Fig. 20 seismically collapsed in 1707 (120 million m^3) and, thereafter, has produced debris flows during many heavy rainfalls. It seems that the strong shaking disturbed the entire mountain body and the rock mass became subject to disintegration more easily after a huge mass of rock fell down and stress

was relieved. Similarly, the slope behind the city of Muzaffarabad in northern Pakistan became unstable after the 2005 earthquake of $M_w = 7.6$; see Fig. 21.

The second type of long-term effect is caused by a huge deposit of debris in mountain valleys. Figure 22 shows a huge mass of debris in a valley.

This debris deposit was produced by slope failures during the 2008 Wenchuan earthquake, China. Since then, the risk of debris flow and avalanche has increased significantly.

Fault-Induced Problems

Fault movement or fault rupture is an important causative mechanism of earthquake shaking and

is classified into normal, reverse, and strike-slip types. Those types of fault depend on the local or regional tectonic stress conditions. Traditionally fault has been a target of scientific study and has not been investigated for engineering purposes. Recently, however, it attracts more engineering concern because of the increasing demands for safety.

Damage Examples

Figure 23 illustrates the destroyed shape of a concrete gravity dam in Taiwan. The energy and

power of fault action overwhelmed the resistance of a massive concrete structure. As such, fault is generally perceived as a formidable natural disaster. In contrast to this idea, Fig. 24 shows the situation around the fault displacement in Taiwan as well. Noteworthy is that the damage was limited within the area of ground distortion, and the houses out of this distortion were not affected. This implies that the essence of fault-induced damage lies in the substantial distortion of ground, while the intensity of shaking is not so significant as may be imagined. Further, Fig. 25

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 23 Shikang Dam in Taiwan after the 1999 Chi-Chi earthquake

indicates the ground distortion caused by an underlying strike-slip fault. The indicated distortion in the surface sandy soil was a consequence and was not the fault action. Therefore, the power of the ground distortion was not significant, and the massive concrete foundation of the house was able to resist the stress exerted by the surface soft soil.

Mitigation of Fault-Induced Damage

One of the measures to avoid the effects of fault displacement is a land-use control by which construction on a known fault line is prohibited. Thus, the area in Fig. 26 remains vacant as a park. The range of control is typically within 15 m from the fault line, as practiced in California and New Zealand. Lifelines, however, cannot sometimes avoid a known fault and may be damaged (Fig. 27). It should be recalled that the Trans-Alaska Pipeline successfully survived the effects of strike-slip action of a fault that it crossed during the 2002 Denali earthquake of $M_w = 7.9$. This success was brought about by the extremely flexible structure that absorbed the fault-induced ground distortion (USGS 2003). Thus, there are two kinds of mitigation, rigid

foundation in Fig. 5 and this soft structure. The shield tunnel for the subway of Osaka City is made of more ductile iron segments at the crossing of the Uemachi fault (Azetori et al. 2006). The Shin-Kobe Station is situated on a normal fault, and the station building is divided into three parts without structural connection among them so that a possible fault movement may not destroy the building. The gravity-type Clyde Dam in New Zealand is divided into two parts across the fault line, and a

concrete key block is installed between them in order to prevent possible leakage of water after fault rupture (Hatton et al. 1991).

Coseismic Subsidence and Uplift

Because earthquakes are induced by rupture and distortion in the earth crust, vertical displacement often remains and affects the society. Figure 28 is the result of the subsidence of the earth crust (coseismic subsidence) after the 2011 gigantic earthquake in Japan.

Geotechnical Earthquake Engineering: Damage Mechanism Observed, Fig. 27 Fault-induced buckling of embedded pipeline (1990 Manjil earthquake of $M_w = 7.4$, Iran)

The lowered ground level leads to difficulty in water drainage and protection from high sea waves. The lowered ground level may or may not be recovered within years. On the contrary, the 1804 Kisagata earthquake of the magnitude being around 7.0 caused uplift and drainage of water from a formerly famous beautiful lagoon. Today, former small islands remain as small mounds in the rice field (Fig. 29).

Liquefaction of Sandy Ground

Soil liquefaction is a phenomenon in which cyclic shear deformation of soil causes high pore water pressure and reduces dramatically the shear rigidity of soil. Liquefied subsoil deforms profoundly and the function of the affected structure is lost. Liquefaction is likely to occur in loose, young, cohesionless, and water-saturated soil that is subjected to strong earthquake shaking. The high pore water pressure induces water flow toward the ground surface and this water flow transports soils. As a consequence, sandy deposits of crater shape remain (Fig. 30).

Typical Liquefaction Damage

The 1964 Niigata earthquake of $M_w = 7.6$ triggered liquefaction-induced damage at many places. Although many liquefaction had occurred in the human history prior to this event, they did not attract engineering concern because they occurred in rice fields, abandoned river channels, etc. Liquefaction became an important problem in the recent time because human settlement

started to expand into areas of poor soil conditions.

Liquefaction causes large deformation of ground and structures. Figure 31 shows subsidence and tilting of a building. Note that the eccentricity of the gravity force (shape of the building) induced tilting. Because consolidation settlement is quick and small in sandy ground, no pile foundation was installed under many

**Geotechnical

buildings, and hence subsoil liquefaction easily induced this damage. Figure 32 depicts the falling down of Showa Bridge. Although the exact cause of this damage is not yet known, liquefaction in the riverbed somehow affected the stability of the bridge foundation. After 1964, much effort was made to understand the mechanism of liquefaction damage and to develop preventive measures as well as assessment of liquefaction risk. By 1980, it had become possible to protect important

structures from liquefaction problems by densification, installing drains and grouting.

Earthfill dams with insufficient compaction are subject to liquefaction as exemplified by the collapse of the Lower San Fernando Dam in California in 1971 caused by the San Fernando earthquake of $M_w = 6.6$ (Seed et al. 1975); see Fig. 33. Moreover, tailings, which are a waste from mining industries, are prone to liquefaction because it is disposed into reservoir water, its

**Geotechnical

grain size is small, being of silty size, and it deposits softly in water to form loose water-saturated cohesionless subsoil. Figure 34 shows an example of liquefaction in a tailings dam.

Although end-bearing pile is an effective protection measure of buildings from subsurface liquefaction, it is not perfect. Because water and sand are ejected after liquefaction (Fig. 30), the volume of subsoil contracts, leading to

consolidation settlement in the ground around a pile-supported building (Fig. 35). Accordingly, lifeline connections are damaged.

Horizontal Displacement of Liquefied Subsoil

Those preventive measures that were developed before 1980 were suitable for important structures for which soil improvement was financially feasible. Since the 1980s, liquefaction problem of

**Geotechnical
Earthquake Engineering:
Damage Mechanism
Observed,**

Fig. 36 Buckling and floating of water pipeline in Dagupan, the Philippines

less expensive structures has attracted concern. For example, a lifeline network cannot improve soil conditions although its possible liquefaction damage affects the entire community significantly. Accordingly, an idea emerged in which the liquefaction-induced damage or deformation should be reduced to an acceptable extent. This idea has developed to the seismic performance-based design in more recent times.

Figure 36 indicates a water pipeline after extensive liquefaction caused by the 1990 Luzon earthquake of surface-wave magnitude = 7.8. The buckling of this pipeline was caused by compressional deformation of the local subsoil. Whether compression or extension, the horizontal deformation and displacement of liquefied ground exert serious effects on underground structures. Hamada et al. (1986) found a

earthquake

liquefied gentle slope to have moved downward and destroyed gas pipelines. Kawamura et al. (1985) reported bending failure of a concrete pile foundation in Niigata where subsoil translated toward the river and the associating lateral displacement of a surface building generated significant bending moment in the pile. Furthermore, in 1995, gravity quay walls moved toward the sea in Kobe and other harbors where backfill soils liquefied (Figs. 37 and 38). The lateral expansion of backfill is evidenced by

many cracks parallel to the quay wall line in Fig. 38.

Liquefaction Problems in the Twenty-First Century

The gigantic earthquake in 2011 in Japan ($M_w = 9.0$) and the sequence of seismic events in New Zealand in 2010 and 2011 caused many liquefaction problems. They are characterized by damage in relatively inexpensive structures such as personal houses, lifelines, and river levees. It is the

**Geotechnical
Earthquake Engineering:
Damage Mechanism
Observed, Fig. 39** House
damage in Christchurch
in 2011

G

case therein that the presently available mitigation technologies have reduced the liquefaction problems of important structures for which financial resource is available for soil improvement. In contrast, individuals cannot afford the cost of perfect soil improvement, which may be too conservative for a small house. Moreover, lifelines and river levees do not have sufficient financial resources either for soil improvement over their long length. Thus, liquefaction problem is still important today.

Figure 39 illustrates a house that tilted because of subsoil liquefaction during the 2011 Christchurch earthquake of $M_w = 6.2$ in New Zealand. Although the damage may not appear serious, minor tilting can cause headache and dizziness to residents. The Christchurch officials declared liquefaction-prone area where all the residents were advised to move to safer places. Figure 40 shows liquefaction-induced tilting and subsidence of a low building resting on a shallow foundation without pile. Figure 41 demonstrates liquefaction in a recent artificial land in Itako, Japan, in 2011. Being different from Christchurch, residents in Japan wish to restore their houses in order to continue to live, while improving the subsoil condition. Apparently, soil

improvement under an existing structure is expensive and time-consuming.

River levee is prone to liquefaction because it is often situated upon water-saturated loose sand. Formerly it was supposed that earthquake resistant design is not always necessary in levees and that seismic damage of levees should be restored within a short time prior to the next flooding. Probabilistically earthquake and flooding are unlikely to occur at the same time. Importantly, levees allow a certain extent of seismic deformation and do not require a strict control of safety. Such an idea started to change in the 1990s. Figure 42 illustrates the damaged shape of Yodo River levee in Osaka City after the 1995 Kobe earthquake. See sand ejecta on the ground surface as an evidence of liquefaction. Because this site is close to the sea where high tide occurs twice a day, a significant subsidence of this levee could have led to overtopping of water and “flooding” in the back area that was lower than the average sea level. Since then, the importance of seismic design of river levees has been recognized under certain circumstances.

During the gigantic earthquake in 2011 in Japan, liquefaction damage occurred in many river levees that were located on clayey subsoil

**Geotechnical

residential area of
Itako City

which was unlikely to liquefy (Sasaki et al. 2012). It was interpreted that the sandy body of the levee caused consolidation settlement in the clayey subsoil, got saturated with water, and developed liquefaction (Fig. 43). Figure 44 illustrates an example of this type of liquefaction in which the original ground surface has no liquefaction in contrast to the significant distortion of the levee.

From the engineering viewpoint, this kind of liquefaction revealed such problems as identification of liquefaction-prone sites, improvement of vulnerable soils, and assessment of seismic performance (assessment of seismically induced deformation), all at reasonable costs.

Buried lifelines are subject to liquefaction problems as well. In particular, liquefaction in

the backfill soil frequently occurs because compaction of the backfill soil around a pipe in a small trench is not easy. Figures 45 and 46 show floating of a pipe and a manhole. Liquefaction

problem of sewerage pipes is more important than that of water supply pipes because the former is embedded at deeper elevation below the groundwater table than the latter and also because

**Geotechnical
Earthquake Engineering:
Damage Mechanism
Observed,**

Fig. 47 Disconnection at sewerage pipe joint and flow-in of liquefied sand (Urayasu City, 2011)

the sewerage water is not pressurized and flows in accordance with the carefully designed slope of pipes; minor change of pipe slope makes the flow difficult. Figure 47 demonstrates one type of liquefaction damage in which a pipe joint was disconnected by large deformation, and the invasion of liquefied sand clogged the water flow.

structures as lifelines, river levees, and residential houses. Because people are demanding a higher level of seismic safety, engineers have to develop methodologies by which their lives and properties are protected from earthquake effects at affordable costs.

Summary

This section reviewed the history of earthquake-induced damage in ground and geotechnical structures, focusing on local soil conditions, intensity of ground shaking, seismic earth pressure, underground structures, slope failures, fault effects, tectonic subsidence, and liquefaction. It is therein seen that the types of damage have been changing with the change of our culture and lifestyles. In particular, liquefaction and lifeline problems were not important 50 years ago and fault problems are now seen as concerns. Another example is the ductile behavior of structures for which the conventional seismic inertial force for design is not good enough. It is therefore important for engineers to pay attention to the changing situation and, when a big earthquake occurs, conduct damage reconnaissance survey in order to detect new types of damage and develop new mitigation measures. Recent earthquakes revealed that earthquake engineering has not yet been helpful for such relatively inexpensive

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of

Masayuki Saeki
Department of Civil Engineering, Tokyo
University of Science, Shinjuku, Japan

Synonyms

Displacement monitoring; GPS (Global Positioning System)

Overview

GNSS (Global Navigation Satellite System) is a satellite-based navigation system. Since it provides accurate position and precise time, the GNSS receiver is employed as a time synchronization device and/or a displacement monitoring sensor in earthquake engineering.

The United States' GPS (Global Positioning System) is one of the operational GNSSs. The constellation of GPS satellites consists of $24 + \alpha$ operational satellites which are deployed in six orbital planes. At least four satellites are arranged in a plane, and several spare satellites are also operated for malfunction. With this constellation, four to eight satellites will be always visible with the elevation mask of 15° . The positioning accuracy reaches to a few meters with point positioning, a few centimeters with kinematic positioning, and a few millimeters with static positioning. Since GPS was at first organized for military purpose, GPS was not perfectly accessible to civil and commercial users. However, SA (Selective Availability) was discontinued in May 2000 to promote its civil use.

In addition to GPS, other GNSS systems are in use or under development. The Russian GLONASS (Global Navigation Satellite System) is also operational GNSS. European Union Galileo positioning system, Chinese Compass navigation system, Indian Regional Navigation Satellite System, and Japanese Quasi-Zenith Satellites are under development as of April 2013.

In the following sections, at first, the concept of GNSS positioning analysis is mentioned. And after that, examples of usage of GNSSs in earthquake engineering are described, such as time synchronization, observation of quasi-static displacements of the Earth's surface, and measurement of the dynamic displacement.

Concept of GNSS Positioning Analysis

Point Positioning and Time Synchronization

A GNSS receiver collects the signals broadcast from the GNSS satellites, which include satellite

navigation information and the precise time when the GNSS satellite emits the signals. As receiving the signals, the receiver estimates the travel time by subtracting the broadcast time from the received time and calculates the range between the receiver and satellite by multiplying the travel time by the propagation velocity. Since an inexpensive crystal clock is employed in the receiver for decreasing its cost, the travel time is contaminated with receiver's clock error. Therefore, the range is called "pseudorange" instead of true range. So, in the point positioning, the receiver's position (x, y, z) and the receiver's clock error dt are treated as unknown parameters.

The receiver calculates the satellite position from the satellite navigation information. Thus, the receiver has the information about the satellites' positions and the ranges from the satellites. So the receiver is able to estimate its position and clock error with the least squares method if more than four GPS satellites are available. It is said that the accuracy of estimated position is about a few to several meters.

Since the velocity of light is about 3.0×10^{-8} m/s, for instance, 3 m error corresponds to 10 ns. So, in this case, the receiver is able to synchronize to the GPS system time with an accuracy of about 10 ns. The GPS system time is derived from the atomic clocks which are implemented in the GPS ground control stations and the GPS satellites. The GPS Navigation Message included in the GPS signals contains parameters that allow the receiver to calculate the correction time from the GPS system time to the UTC (Universal Time Coordinated) with the accuracy of sub-microsecond order (Dana 1997). Therefore, the GPS receiver for time synchronization provides the precise UTC time.

Interferometry Positioning (Static and Kinematic Positioning)

In order to achieve an accuracy of a few or sub-centimeters, interferometry positioning technique is needed. In the interferometry positioning, phase of the carrier wave is analyzed instead of the code pseudorange. The carrier phase (expressed in cycles) multiplied by the

wavelength gives the information associated with the distance between the receiver and satellite. Since the wavelength is about 19.0 cm in case of L1 carrier wave and the phase can be determined with an accuracy of 1–0.1 %, the range can be estimated less than 2 mm accuracy. This phase pseudorange enables us to estimate the receiver position with an accuracy of a few millimeters. However, how many cycles exist in the range is unknown. So there is an ambiguity in phase pseudorange. This ambiguity is called "phase ambiguity" or "integer ambiguity" and treated as unknown parameters should be estimated as an integer value.

The phase pseudorange between receiver i and satellite k is generally described as the following equation:

$$\phi_i^k = \rho_i^k + \lambda N_i^k + c\Delta t_i + c\Delta t^k + \Delta_{trop,i}^k - \Delta_{ion,i}^k + \Delta_{ant,i}^k + \varepsilon_i^k$$

where ϕ_i^k is the phase in meters, ρ_i^k is the true range, λ is wavelength, N_i^k is the phase ambiguity (or called integer ambiguity), Δt_i is clock error of receiver, Δt^k is clock error of satellite, $\Delta_{trop,i}^k$ is tropospheric delay, $\Delta_{ion,i}^k$ is ionospheric delay, and $\Delta_{ant,i}^k$ is error related to the antenna including antenna phase center variation and multipath noise. The true range ρ_i^k is expressed as

$$\rho_i^k = \|\mathbf{x}_i - \mathbf{X}^k\| = \sqrt{(x_i - X^k)^2 + (y_i - Y^k)^2 + (z_i - Z^k)^2}$$

where $\mathbf{x}_i = (x_i, y_i, z_i)$ is the GPS antenna position and $\mathbf{X}^k = (X^k, Y^k, Z^k)$ is the satellite position.

To eliminate the clock errors related to the receiver and satellite, the double-difference operation is used in the relative positioning. In this method, the relative position from a base station is accurately estimated. The DD (double-differenced) phase pseudorange is expressed as the following equation:

$$\phi_{ij}^{kl} = \rho_{ij}^{kl} + \lambda N_{ij}^{kl} + \Delta_{trop,ij}^{kl} - \Delta_{ion,ij}^{kl} + \Delta_{ant,ij}^{kl} + \varepsilon_{ij}^{kl}$$

where

$$*_{ij}^{kl} = *_{i}^k - *_{j}^k - \left(*_{i}^l - *_{j}^l \right)$$

If the baseline is short enough to assume that the measured phases are equally affected by the troposphere and ionosphere at both receivers, $\Delta_{trop, ij}^{kl}$ and $\Delta_{ion, ij}^{kl}$ are also canceled through the double-difference operation. However, such assumption is generally incorrect in case of determining the crustal deformation, because the baseline is generally over a few to tens of kilometers.

Δ_{trop} is estimated with a mathematical model such as Hopfield model, modified Hopfield models, and Saastamoinen model. In these models, the tropospheric delay in zenith direction is estimated first and is multiplied by the mapping function which represents the effect of elevation angle. For more precise application, Δ_{trop} is treated as an unknown parameter. The ionospheric delay Δ_{ion} also can be calculated with a mathematical model, but it is efficiently eliminated using the combination of L1 and L2 frequency measurements (Hofmann-Wellenhof et al. 1994). Therefore, L1/L2 GPS receiver is commonly used for determining the crustal deformation. L1 GPS receiver is used only in the case of short baseline.

In the DD phase pseudorange equation, the receiver position $\mathbf{x}_i$ and DD integer ambiguities N_{ij}^{kl} are unknown. If n satellites are available, $3+(n-1) = n+2$ unknowns should be solved although only $n-1$ equations are there at a single epoch. Therefore, in general, equations obtained at different epochs are solved together with the least squares method or Kalman filter. The solutions are called “float solution,” and the integer ambiguity should be resolved as an integer value. LAMBDA method is the most famous method for determining integer ambiguities (Teunissen et al. 1997).

In the relative positioning, relative position from a base station is estimated. Therefore, if the base station and observation point are close to each other, these points are equally displaced due to earthquake and the relative position cannot be observed. So, to measure the displacement due to earthquake, the base station is selected enough far from the observation points. It is said that the

accuracy is correlated with the baseline length and amounts to 1–0.1 ppm for baselines up to some 100 km and even better for longer baselines in case of static positioning (Hofmann-Wellenhof et al. 1994).

The static positioning is generally employed when coseismic, postseismic, and interseismic displacement is estimated. In this analysis, the unknown parameters (x, y, z) are treated as constant value and several hours measurements are analyzed together in a single batch. Since the effects of various noises are averaged, the accuracy reaches to a few millimeters. On the other hand, if the seismogram or dynamic motion is needed, kinematic positioning is applied. In this case, the unknown parameters (x, y, z) are treated as time-dependent variables and generally estimated with Kalman filter. The accuracy is said to be a few centimeters or worse. For the rapid use such as earthquake early warning, RTK (Real Time Kinematic) positioning is used. In the kinematic positioning, since the analysis is carried out in the postprocessing manner, relatively high accurate satellites’ orbit or additional constraints can be involved in the analysis. However, in the RTK GPS, the kinematic positioning is timely carried out following an earthquake event. As a result, the accuracy is relatively worse than that of the kinematic positioning.

Example of Time Synchronization

As mentioned in the previous section, the GPS receiver for time synchronization is able to output timing precisely synchronized to UTC. This enables us to observe seismogram with synchronized clocks at many stations extremely far from each other.

The National Research Institute for Earth Science and Disaster Prevention (NIED) has developed and maintained the nation-wide high-sensitivity seismograph network called “Hi-net” (High Sensitivity Seismograph Network in Japan). In this system, the seismic data originally sampled at 1 or 2 kHz is decimated to 100 Hz and created a data packet of 1 s length to which a GPS time stamp is added (Okada et al. 2004).

Examples of Static Displacement Determination with GNSS

Displacements of the Earth's surface are monitored with permanent GNSS networks. The determined displacement vectors are used for studying crustal deformation associated with earthquakes, determining the geometry of fault plane, and estimating strain accumulation.

Permanent GNSS Networks

IGS (the International GNSS Service) operates an international network of over 350 continuously operating dual-frequency GPS stations and collects GPS and GLONASS observation data sets. These data sets are analyzed and combined to form the IGS products. The primary IGS products are the GPS satellites' IGS final orbit and clock corrections. These accuracies are within 5 cm and 0.1 ns, respectively (Dow et al. 2009). Any users are freely accessible to the orbit data on line. Geocentric coordinates of IGS Tracking Stations are weekly updated and also provided (IGS HP 2013).

GEONET (GNSS Earth Observation Network System) is the largest continuous GNSS network that is operated by GSI (the Geospatial Information Authority of Japan). The GSI operates GNSS-based control stations that cover Japanese country with over 1,200 stations at an average interval of about 20 km. The GPS and GLONASS observation data are sampled at 1 s interval. The 1 Hz sampling data sets and the data sets resampled at 30 s interval are both available online for actual survey work in Japan as well as studies of earthquakes and volcanic activities (GSI HP 2013).

Coseismic, Postseismic, and Interseismic Displacement

It is considered that there are spatial variations in the degree of coupling on the fault plane (asperity model). This means that some parts on the fault plane are strongly coupled and the other parts slowly slip or rupture at relatively small earthquakes. As the plates are moved, the crustal deformation occurs and strains are accumulated around the strongly coupled zone. The

accumulated strain will be released at a large earthquake. Therefore, strain accumulation monitoring is very important to assess earthquake potential. The strain accumulation and its release are estimated by analyzing the data measured by seismograph, tiltmeter, leveling, and the permanent GPS networks.

Coseismic displacements have been measured for studying geometry of fault surface. The surface displacement of the Earth is associated with the slip on the fault surface through mathematical models. The radiated seismic wave field is dependent on the slip amplitude, rupture velocity, and source time function, whereas the quasi-static displacements depend only on the final slip amplitude. Therefore, the displacements measured with GNSS are complementary constraints on the geometry of fault surface (Segall and Davis 1997).

Hudnut et al. (2002) observe the postseismic displacements associated with the 1999 Hector Mine earthquake using the rapidly deployed continuous GPS network and SCIGN (Southern California Integrated GPS Network) stations and analyze the temporal character and spatial pattern of the postseismic transients. They report that the displacements measured at some sites display statistically significant time variation in their velocity.

Ozawa et al. (2011) investigates the spatial distribution of the coseismic and postseismic slips associated with the 2011 Tohoku earthquake (Mw9.0, March 11) by analyzing the ground displacement detected using the GEONET and reports that the detected coseismic slip area matches the area of the pre-seismic locked zone.

At subduction zones, slow-slip events have been detected by geodetic measurements in interseismic period. Hirose and Obara (2005) report the repeating occurrence of short-term and long-term slow-slip events which are accompanied by deep tremor activity around the Bungo Channel region, southwest Japan. They detect these activities using NIED Hi-net equipped with a tiltmeter and a high-sensitivity seismograph and GPS stations of GEONET. The GPS is only used to detect the long-term slow-slip events because the short-term slow-slip event is too small in magnitude to be detected by GNSS.

Examples of Dynamic Displacement Determination with GNSS

The permanent GNSS network is used to measure dynamic displacements as well as static displacements.

Strong Motion

Strong motion associated with a large earthquake is generally observed with seismograph that is inertial sensor and sensitive to acceleration. Therefore, higher frequency components can be detected accurately with the sensor, but the lower frequency components are not detectable and largely contaminated by random noise. Furthermore, if the seismograph is tilted during a large earthquake, the observed acceleration has offset due to the gravitational force. Therefore, the dynamic displacement estimated with the double integration of acceleration diverges proportional to the square of time. Sensor rotation also distorts the measurements. So it is very difficult to detect long-term displacements with inertial sensor measurements. On the other hand, GNSS sensor directly detects the displacement itself. Besides, some GPS receiver is able to sample the data up to 20–50 Hz. From these reasons, GPS sensor is also used for monitoring dynamic displacements. The accuracy (standard deviation) is said to be a few centimeters in horizontal direction and about two times larger in the vertical direction.

Nikolaidis (2001) et al. report that the dynamic ground displacement caused by the Hector Mine earthquake in southern California (Mw 7.1, October 16, 1999) is determined by analyzing the GPS data collected with SCIGN continuous GPS network. The baseline distances are from 53 to 205 km. In this research, the raw GPS data is analyzed with instantaneous positioning method to obtain displacement time series, while kinematic positioning is generally used. In the instantaneous positioning method, integer ambiguities are resolved independently for each epoch. Hence, the analysis is not affected by the cycle slips of phase measurements.

Dynamic displacements obtained from GPS network are used in the inversion for rupture processes. The dynamic displacements include

coseismic displacement as well as lower frequency components. So it is expected to merge the seismic wave inversion and geodetic observation inversion. Yue and Lay (2011) estimate the rupture process of the 2011 Tohoku earthquake (Mw 9.0, March 11) using 1 Hz sampling GPS data measured with GEONET.

Tsunami

Kato et al. (2000) develop a tsunami observation system using RTK GPS to detect a tsunami before it reaches the coast. This system consists of the Support-buoy, the Sensor-buoy, and the base station. The Sensor-buoy is designed not to react to wind wave motion and is equipped with only GPS antenna. The antenna cable is connected to the GPS receiver mounted on the Support-buoy. The Support-buoy is designed to move with wind waves and is equipped with GPS receivers and antenna, a number of sealed lead batteries, a wind generator, solar panels for power supply, and a pair of radio receiver and transmitter devices. Their experimental results show that the developed system is able to track the sea surface quite well.

Examples of Disaster Mitigation with GNSS

Early Warning System

Allen and Ziv (2011) investigate the possibility of application of RTK GPS to earthquake early warning using the data collected in the El Mayor-Cucapah earthquake in northern Baja California (Mw 7.2, 2010). Earthquake early warning is the rapid detection of a large earthquake and prediction of the expected ground shaking within seconds so that a warning can be broadcast to the nation. In general, earthquake early warning system estimates the magnitude of an earthquake with seismic waves observed around the epicenter. The problem of how accurate the magnitude is estimated with only seismic waves for a large earthquake is considered. The unique information provided by the GNSS-based displacement time series is the coseismic displacement that is hardly obtained from acceleration

time series. This information is expected to provide effective constraints to the magnitude estimation.

A GPS-based tsunami early warning component, developed by the German Research Centre for Geosciences (GFZ) within the German-Indonesian Tsunami Early Warning System (GITEWS) project, was installed in Indonesia after the disastrous Indian Ocean tsunami (December 26, 2004). This component consists of four subcomponents; the GPS real-time reference stations (GPS RTR) for ground motion detection and reference station for buoy GPS receivers; GPS sensor stations at tide gauges for ground motion detection and tide gauge data correction; GPS sensors on buoys for sea level measurements and direct tsunami detection; and external GPS stations for providing external reference frame. At a large earthquake, GPS data is transmitted from GPS stations in near real time, and displacements are determined. The ground displacements are used to select the most probable tsunami scenario from some thousands of pre-calculated scenarios, based on a matching process. The sea level height is determined by analyzing the GPS data from offshore buoys to detect tsunami directly (Falck et al. 2010).

Postseismic Damage Detection

Application of the GPS wireless sensor network (GWSN) to postseismic building-wise damage detection is studied. The details of GWSN are described in the later section.

The GWSN consists of a central server and many sensor nodes. The sensor node has a wireless communication module, microcontroller, small battery, and inexpensive L1 GPS module connected to a small patch antenna. At a large earthquake, the sensor nodes collect raw GPS data according to the command from a central server and share the collected data between the neighboring sensor nodes. After that, the sensor nodes determine the relative position from the neighboring sensor nodes onboard and transmit the estimated relative positions to the central server through wireless communication network. The central server combines the relative positions to organize the sensor mesh and detects the

displacements of each sensor. From the estimated displacements, the useful information about the building collapses and road closures due to the debris is investigated for the early stage of the rescue action after a large earthquake (Oguni et al. 2011).

Summary

GNSS is a very useful system in earthquake engineering because it enables us to determine the displacements due to earthquake at any point wherever the antenna and receiver are properly deployed. The estimated coseismic, postseismic, and interseismic displacements are used for determining the geometry of fault plane and rupture process, estimating the magnitude of earthquake, and estimating the future earthquake potential. This helps our understanding of earthquake. GNSS is also used as a time synchronization system for seismograph network.

GNSS receiver is employed as a displacement sensor in various systems for disaster mitigation. A GPS-based tsunami early warning system is installed in Indonesia. And other tsunami early warning systems are studied. Earthquake early warning system with RTK GPS and postseismic building-wise damage detection system are also studied.

As of April 2013, only the United States' GPS and Russian GLONASS are fully operational GNSSs. In the near future, European Union Galileo positioning system, Chinese Compass navigation system, Indian Regional Navigation Satellite System, and Japanese Quasi-Zenith Satellites will join in the fully operational GNSSs. Therefore, the accuracy and robustness of the system with GNSS are expected to be improved further.

GPS Wireless Sensor Network

System Overview

Wireless sensor network is a system in which many wireless sensor nodes automatically organize and maintain a wireless network and

transmit their data or information to each other. The sensor node consists of a microcontroller, physical sensor, low power radio module, and small battery. In the GPS wireless sensor network (GWSN), an inexpensive L1 GPS receiver connected to a small patch antenna is employed as the physical sensor (Saeki et al. 2006). Figure 1 shows a prototype of the sensor node.

This prototype employs a wireless communication module having a 32 bit microcomputer, 128 kbyte RAM, several serial communication ports, as well as an RFIC (Radio Frequency Integrated Circuit) based on IEEE802.15.4.

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 1 Wireless sensor node equipped with an inexpensive L1 GPS module connected to a small patch antenna

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 2 A schematic view of the GWSN (GPS wireless sensor network)

The electric current is 14.6 mA (3.0 V) at receiving data and 17.4 mA at transmitting data. This kind of wireless communication module has some sleep modes depending on usable functions, and the electric current reaches at a few μ A in the deep sleep mode.

An inexpensive L1 GPS module is connected to the wireless sensor module through a serial communication. The electric current is about 50 mA (3 V) which is highest among the electric components of the prototype. In the prototype, a small patch antenna is employed, which is generally never used for the precise displacement determination because such a small patch antenna has weak directivity and then the data is largely affected by the multipath noises. This noise contamination makes it difficult to resolve the integer ambiguities.

A schematic view of GWSN is shown in Fig. 2. This system consists of many sensor nodes and a central server. The sensor nodes are ordinarily in sleep mode for saving their battery energy. They wake up, for example, every 1 min to ask their task to the server. If the task is “sleep,” they go into sleep mode again. If the task is “observation,” they turn the GPS module on and wait a trigger signal. After receiving the

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 3 A format of compressed data of a single epoch in case of static relative positioning with short baseline

trigger signal, the sensor nodes save the required raw GPS data on their RAM during a specified time interval. After finishing data acquisition, they turn the GPS module off and return back to sleep mode. If the received task is “data collection,” the sensor node sends the saved GPS data to the server through wireless communication. The sampling interval and data length can be changed according to the command from server.

Data Compression Technique

Data compression is a very important technology for wireless sensor network, because a large amount of data requires long communication time and high energy consumption which results in short battery lifetime. For example, if a GPS module outputs about 300 bytes per epoch (practically the data size of original message depends on the type of GPS module) and a sensor node saves the whole data for 10 min, the amount of data reaches to 180 kbyte. It takes about 18 s for a sensor node to transmit the data to the server with a transmit rate of 100 kbps. If a single server covers 100 sensor nodes, it needs at least 30 min (=1,800 s) to collect data from all sensor nodes. (GWSN for the application of building-wise damage detection is specially customized so that the sensor nodes locally share their data between neighboring sensor nodes, estimate their relative position onboard, and transmit only the estimated results to the server to avoid transmitting large amount of data.) Since the original raw GPS data is large in amount, truly required data should be extracted. Figure 3 shows a format of compressed data packet.

In the GWSN, quasi-static condition is assumed, which means a relative position of sensor nodes is invariant during the short observation period (e.g., 10 min). The quasi-static assumption and dense sensor deployment enable us to omit the data of code pseudorange and integer part of phase pseudorange. As a result, the amount of data can be drastically decreased to 28 byte per epoch (Saeki et al. 2006).

The integer part of phase pseudorange is very important information especially for kinematic positioning. As mentioned above, the phase pseudorange includes phase ambiguity as unknown value. The value of phase ambiguity is constant as long as the GPS module continuously tracks the satellite’s carrier waves. If the integer part of phase pseudorange is missed, the phase ambiguity becomes different value and should be determined again. This phenomenon is called “cycle slip” and recognized as an important problem to be solved.

On the other hand, in case of static positioning, the missing integer part can be fixed by shifting the corrected DD phase pseudorange $\hat{\phi}_{ij}^{kl}(t)$ (appears in the following section) by integer value so that the difference between the successive two values is minimized. This is because the corrected DD phase pseudorange can be approximated as a linear function of time with a small slope in case that the relative position of sensor nodes is invariant and the baseline is short enough. Figure 4 shows an example of the corrected DD phase pseudorange. The fluctuation is less than 0.2 cycles after repairing the cycle slips.

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 4 An example of the corrected DD (double-differenced) phase pseudorange in case of short baseline and static condition

Static Positioning Using Linear Approximation Method

Since energy consumption of GPS module is highest among the electric components of the sensor node, it is effective to shorten the acquisition time of GPS for saving battery energy. However, in general, short data length makes it difficult to successfully determine phase ambiguities. The wrong phase ambiguities largely deteriorate the accuracy of positioning. Therefore, an algorithm improving the success rate of phase ambiguity determination with short data length is required to solve the trade-off relationship between the energy consumption and accuracy.

At first, a conventional approach is described here. The observation equation of DD phase pseudorange can be linearized by substituting $\mathbf{x}_i = \hat{\mathbf{x}}_i + \Delta\mathbf{x}$ into the equation of ϕ_{ij}^{kl} .

$$\phi_{ij}^{kl} = \hat{\rho}_{ij}^{kl} + \nabla\hat{\rho}_{ij}^{kl} \cdot \Delta\mathbf{x} + \lambda N_{ij}^{kl} + e_{ij}^{kl}$$

where $\hat{\rho}_{ij}^{kl}$ is the calculated DD range between the approximate position of GPS antenna $\hat{\mathbf{x}}_i$ and the GPS satellite position and e_{ij}^{kl} is the noise including residuals of DD ionospheric and tropospheric delay, antenna noise, and random noise. The equations obtained for available satellites provide the following simultaneous equation:

$$\mathbf{U}(t) = A(t)\Delta\mathbf{x} + \lambda\mathbf{N} + \mathbf{e}(t)$$

where $\mathbf{U}(t)$ is the vector of corrected DD phase pseudorange defined as $\hat{\phi}_{ij}^{kl} = \phi_{ij}^{kl} - \hat{\rho}_{ij}^{kl}$, $A(t)$ is the design matrix, $\mathbf{N}$ is the vector of DD phase ambiguities N_{ij}^{kl} , and $\mathbf{e}(t)$ is the vector of noise $e_{ij}^{kl}(t)$.

The above simultaneous equation is generally solved by using Kalman filter. The solution is

called “float solution” because the phase ambiguities are determined as float values. Accurate position can be estimated after resolving the phase ambiguities as integer values. The resolved integer values are called “fixed solution,” which is searched so that the following objective function J is minimized:

$$J = (\mathbf{N} - \hat{\mathbf{N}})^T Q_{\hat{\mathbf{N}}}^{-1} (\mathbf{N} - \hat{\mathbf{N}})$$

where $\hat{\mathbf{N}}$ is the float solution of phase ambiguity vector and $Q_{\hat{\mathbf{N}}}$ is the variance-covariance matrix of the float solution. The fixed solution is validated by checking the ratio J_2/J_1 where J_1 and J_2 are the minimum and the second minimum residuals, respectively. It is said that the integer ambiguity may be successfully resolved if the ratio J_2/J_1 is greater than 3–5.

As mentioned in the previous section, the corrected DD phase pseudorange $\hat{\phi}_{ij}^{kl}(t)$ can be modeled as a linear function of time. So, in the positioning analysis of GWSN, a linear function is approximately estimated by applying least squares method to the time series of corrected DD phase pseudorange. And the values corresponding to the first and last epochs are calculated using the estimated linear function. The observation equations only at the first and last epochs are solved together with least squares method to estimate the position and DD phase ambiguities. This method may slightly improve the quality of coefficient matrix of normal equation and suppress the effect of noises on the solution.

The success rate of determining the DD phase ambiguities can be improved by using the linear approximation method, especially in case of short data length. Table 1 shows the comparison between the results of the conventional approach (static positioning) and the described method. The observation data used in the analysis was collected under ideal condition in which no obstacles were over there. In this experiment, GPS antennas for survey work were fixed on tripods, and GPS data was logged over 24 h with a 1 Hz sampling rate. In the analysis, data segment with a specified data length was selected

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Table 1 Comparison between success rates of the static positioning and the linear approximation method (Saeki et al. 2006)

Data length (s)	Success rate (%)	
	Static positioning	Linear approximation
30	71.1	87.3
60	89.8	96.0
180	98.7	99.1
300	99.5	99.6
600	100.0	100.0

and analyzed using both the conventional and the linear approximation approaches. This estimation was performed 86,400 times by shifting the selected data by 1 s.

Multi-hop Positioning

The observation equation of DD phase pseudorange is solved with the assumption of white noise. This assumption may be valid for some pairs of sensor nodes existing under similar surrounding condition because such condition gives similar multipath noises and the noises are canceled out in the double-difference operation. However, for the pairs existing under different condition, multipath noises are different and not canceled out in double-difference operation. In this case, the accuracy of float solution becomes worse, and the DD phase ambiguities are not successfully resolved as integer value. Therefore, it is meaningful to select a good pair of sensor nodes whose noises are similar to each other.

Figure 5 shows a simple example of relative position determination. Suppose that three sensor nodes are there and the noises are different from each other but the noise of ID3 has some similarities to those of ID1 and ID2. This situation often happens in actual observations when many sensor nodes are deployed densely. In this case, the relative position from ID1 to ID2 tends to be estimated incorrectly, and the ratio J_2/J_1 becomes small (as described in Fig. 5a) because the noises are not canceled out in the double-difference operation. On the other hand, the vector ID1 → ID3, and also the vector ID3 → ID2, may be estimated better and the ratio becomes larger

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 5 Simple example of (a) relative position vectors from a single reference point and (b) estimated position vectors by using the multi-hop positioning

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 6 Function of success probability with respect to the value of ratio test (Saeki 2012)

(Fig. 5b). In this case, the sum of vectors ID1 → ID3 and ID3 → ID2 is more likely to give better solution. This is a basic idea of multi-hop positioning (Saeki and Oguni 2012).

To select an optimum path quantitatively among the candidates (possible sum of vectors), success probability function $P(r)$ is introduced. It is empirically known that higher ratio J_2/J_1 ($= r$) gives higher success probability. Figure 6 shows the experimental results of the success probability versus the ratio J_2/J_1 . The marks represent the results obtained from an experiment, and the lines are the fitted curves using the function $P(r) = 1.0 - be^{-ar}$ where a and b are the fitting parameters. The experiment was conducted

Global Navigation Satellite System (GNSS) in Earthquake Engineering, Usage of, Fig. 7 Relative position vectors determined by Dijkstra's algorithm

under an ideal condition (no obstacles over the site), but the GPS antennas were differently fixed. In the first pair (exp.1) the antennas were both fixed on a flat concrete floor. In the second pair (exp.2) one antenna was fixed on a flat concrete floor, but another one was attached on a concrete block with a height of 15 cm. This difference gave slightly different multipath noises. In the third pair (exp.3) one antenna was fixed on a flat concrete floor, but another one was fixed on a tripod. In this case, the multipath noises were very different to each other.

The success probability of path can be evaluated by multiplying the success probabilities of the corresponding vectors.

$$P(r) = P(r_1)P(r_2) \cdots P(r_n)$$

The optimal path is searched from numerous candidates so that the success probability is maximized. In the multi-hop positioning, Dijkstra's algorithm is used as a search algorithm. This algorithm is widely used in many applications such as network routing protocols or mobile navigation systems to find the shortest (or lowest cost) path efficiently.

Figure 7 shows an experimental result of the optimum path estimated using the multi-hop positioning method. In the experiment, 53 sensor nodes were arranged on a rooftop of a building in a grid form at 2 m spaces. The raw GPS data was saved for 4 min with 1 Hz sampling rate and transmitted to the central server through wireless communication. The multi-hop positioning was

applied in postprocessing manner to estimate the best relative positions of sensor nodes which maximized the success probabilities.

Introduction

This entry looks at a review of seismic-resistant codes for each country in the world by examining

The online version includes code changes and code types through time.

the historical changes of codes from 1900 to 2013, the years in which updates were made, the number of buildings these codes influence, and a review of the code quality itself with respect to the hazard of that country. Over 160 countries and nations have some form of seismic code. However, the quality, extent of application, and methodologies between seismic-resistant codes differ around the world. An exploration of the location of each of these code changes, in terms of when they have been implemented, to what extent they have been implemented, and which percentage of buildings they encompass, has been undertaken.

The History of Seismic-Resistant Codes Worldwide and Their Components

Seismic-resistant building codes traditionally started being implemented during reconstruction following major earthquakes of the past, including 1755 Lisbon, 1880 Luzon, and 1908 Messina. Although no country had a formal seismic-resistant code in 1900, some countries such as Italy, Portugal, the USA, and other locations had influences from historical earthquakes, which aided the building styles of the time being more seismic resistant. This was also the case with colonial building styles in Africa. Using the components of lateral earthquake forces, ductility and drift and building height, these were slowly implemented into design, as explained in the previous chapter of Gülkan and Reitherman.

The first seismic-resistant codes simply applied a seismic coefficient and building height limits, such as those implemented within Italy (1910, 1917), Costa Rica (1914), Turkey and Japan (1923), the USA (1906, 1927), and other locations pre-1930s. It should be noted that, pre-1930, some municipalities and cities applied different seismic-resistant building codes or practices, such as building from wood after the 1848 Wellington earthquake (Beattie and Thurston 2006) or after the 1770 Haiti earthquake.

Lateral loads were often included with the wind, snow, and gravity loads in analysis.

Post-1930, the difference of the response spectrum to various structural periods was looked at, with the influence being that the lateral forces would be changed depending on the fundamental period of the building. Elastic analysis was, however, still undertaken, as opposed to elastoplastic analysis (ductile analysis).

Only in the 1960s were ductility considerations taken into account in the form of force-reduction factors, given that ductile structures were able to survive ground shaking and thus inertia forces many times greater than elastic structures. These force-reduction factors were placed slowly into the seismic-resistant codes in different countries from the 1970s to 1990s; however, greater research in the field showed the need for analysis into the effects of damage potential as a result of displacements rather than strength alone.

There were also two types of building analysis undertaken: force-based design and displacement-based design. Force-based design uses a seismic coefficient (C) and a seismic weight (W) calculated to give the design seismic forces (V):

$$V = C_s * W, \quad \text{where}$$

$$C_s = S_a / (\text{Reduction Factor} / \text{Importance Factor})$$

The seismic coefficient is made up of the design spectra of the earthquake horizontal and vertical components calculated from various parameters detailed in Table 1 below, in combination with a reduction factor corresponding to the global ductility capacity and the inherent overstrength in the lateral force-resisting system. Using this system generally works; however, it relies on the fact that strength is being used to control damage and that strength and stiffness are independent. In reality, these two are interlinked. Force-reduction factors assume that the ductility demand is the same for each type of structure unless changed; however, each building generally acts differently with respect to ductility. The distribution of strength in a building, including

the amount of displacement at different limit states, has been determined to be increasingly important, despite both methods looking at the location of plastic hinges (shear strength of members being greater than that of the shear due to flexural strength) and hence looking at the displacement ductility of the components of the building or structure. The previous chapter of Gülkan and Reitherman provides a useful background to the implementation of such parameters.

These difficulties resulted in displacement-based design, rather than force-based design, being undertaken in order to construct buildings safely (Priestley et al. 2007). Displacement-based design is still generally not used in seismic codes but can be applied as a valid alternative where wanted. A comment to this effect has been incorporated in the NZS code 1170 Part 5 (Standards New Zealand 2004).

Thus, there are now two main types of seismic codes used worldwide. The first, strength-based design, relies on a design base shear with force-based design generally based on historical earthquake hazard maps, without any view as to the performance of the structure in different events. The other, performance-based design, still uses these uniform spectra metrics from seismic zoning and traditional force-based design but adds in performance criteria that need to be satisfied at more than one earthquake level. In this way, performance levels are also defined differently for schools versus normal buildings, as a different return period can be defined for the performance, thus designating different displacements or interstory drifts required. Better levels of performance-based design are creeping slowly into revisions of seismic-resistant codes worldwide, with life safety and damage limitation of buildings at various corresponding levels of earthquake motions being implemented and even displacement-based design (Priestley 1993) being included.

Table 1 represents the key elements of a modern seismic-resistant code, which then will be summarized for the purposes of the seismic code index developed.

Global View of Seismic Code and Building Practice Factors, Table 1 The criteria examined for each of the seismic-resistant codes within the worldwide seismic code index (1900–2012) discussed in this study

Element	Sub-element	Key components	Value given out of 104
Structural design method	Material loads/strengths, dead and live load	Basic principles of design as denoted by the general building code in the country	30
Seismic actions	Horizontal components	Design response spectra (S_a) generally determined by the ground seismic acceleration, importance factor, at characteristic design periods, damping modification factor. It has different shapes for design periods, depending on these cutoffs	5
Seismic actions	Vertical components	Generally taken as a percentage of the horizontal factor to create A_v	3
Seismic actions	Ground seismic acceleration	Acceleration at which the seismic zone map coefficient will occur for a return period (475 years generally) Can be intensity or PGA based	Included as a percentage of actuality over 30
Seismic actions	Near fault	Looks at whether near-fault effects are taken into account	2
Seismic actions	Soil classification	Depending on soil type, extra factors applied to account for the increased shaking	5
Seismic actions	Importance factor	Structures generally split into various factors in order to define different levels of design in terms of life safety, e.g., hospitals given a higher level of safety	5
Seismic actions	Behavior factor (ductility factor)	Reduction of seismic loads based on post-elastic behavior – depending on the material of the structural system	5
Seismic actions	Foundation factor	Interaction between the foundation and the soil is included in some cases	5
	Existing buildings		% of buildings
	1–2-story building factor		% of buildings
Design method	Simplified spectrum method	Uses the fundamental mode of oscillation and looks at equivalent seismic forces. Simplified and does not take into account so many complexities, just using base shear multiplied by the design spectra value and distributing the lateral forces over the height of the building Also includes eccentricities, other loading details	5
Design method	Drift	Drift is used to calculate seismic forces as a boundary condition	2
Design method	Dynamic response method	Uses dynamic response spectrum method, taking into account multiple modes of oscillation, which has higher quality until the sum of effective modal masses reaches a certain percentage of the oscillating mass of the system	5
Design criteria	Nonstructural	Are nonstructural elements designed for?	2
Design criteria	Avoidance of collapse	Special notes with application to the earthquake load combination, avoidance of soft-story mechanisms, plastic hinge locations, and other combinations	5
Design criteria	Damage limitation	Load-bearing systems, pounding taken into account, drift, appendages such as chimney, facades	5

(continued)

Global View of Seismic Code and Building Practice Factors, Table 1 (continued)

Element	Sub-element	Key components	Value given out of 104
Foundation design	Foundations, retaining structures, slopes	Basic checks as to slope stability and other foundation design applications such as liquefaction hazard, shear settlement, differences for shallow and deep foundations, etc.	5
Code quality assessment	Displacement-based design/overall	Displacement-based criteria in terms of the design methodology or overengineered status, additional components and methodologies encompassing many design levels for all types of structures	15

Global View of Seismic Code and Building Practice Factors,

Fig. 1 The number of countries with a seismic-resistant code/zonation as of 2013 borders

Which Countries Have Seismic Codes?

Not all countries have seismic codes; however, documentation does not exist on a global scale to see which countries have seismic-resistant codes and whether they are part of law, enforced or ignored. In addition, some countries have differences on the province-level enforcement or adherence to such codes.

In order to determine the factor by which damage is changing and the complexity of codes, a significant review and analysis was undertaken to create a harmonized up-to-date list of locations where seismic-resistant codes have been considered. There were several early initiatives which attempted to undertake this by looking at only a list of some of the countries worldwide with seismic-resistant building codes, including the World List initiative by the IAEE which includes details as to some seismic-resistant codes in various countries – IISSE

1992, 1996, 2000, 2004, 2008, and 2012 (IAEE 1996, 2000, 2013). In addition, there has been a list of countries which have some form of seismic codes in the practice of earthquake hazard assessment (92 countries) (McGuire 1993). The “Seismic Code Evaluation” work in Central America as well as South America has been collected and implemented in the database (Chin and Association of Caribbean States 2003).

One hundred and sixty-six nations out of two hundred and forty-four nations have some form of seismic-resistant code, but they are usually not implemented for all styles of buildings, given the large number of nonengineered building styles worldwide as shown in Fig. 1.

In addition, there are nations which have some form of code; however, this has not been ratified and has not been implemented in practice. For earthquakes, a review of the various seismic-resistant codes around the world has been

Global View of Seismic Code and Building Practice Factors, Fig. 2 The seismic zonation changes for the country of Macedonia (Salic et al. 2010)

Global View of Seismic Code and Building Practice Factors, Fig. 3 The number of countries with code changes and updates since 1900

undertaken, examining the level of base shear relative to hazard, seismic zoning, and other parameters ranked in comparison to the relative hazard of a particular country versus the seismic hazard actually represented.

Many different countries have had multiple editions, adjustments, and changes to their seismic-resistant codes and zonations in the past

century. Studies such as Salic et al. (2010), as depicted in Fig. 2 for Macedonia, or Romeo (2007) for Italy show the move from seismic hazard based on historic earthquakes to probabilistic hazard with a smoothing of hazard zonations used in code through time.

Shown in Fig. 3 are the number of code changes through time for each nation.

Global View of Seismic Code and Building Practice Factors, Fig. 4 The worldwide seismic code index (level 1) as calculated for 2012, showing the quality of the

seismic-resistant and/or building code (or lack thereof) in each country regardless of enforcement and building practice factor

The seismic code index ranks the quality of seismic codes since 1900 in each nation, giving a score between 0 and 104, normalized to 100 as two extra components were added later (Daniell et al. 2011). The criteria was set that a country with a unified national code was placed at a value of 30/100, utilizing the minimum criteria set which is the use of earthquake loading in some form of design (not necessarily for all structures). The quality of this code was then objectively ranked by using the above criteria elements to make an assessment of the code quality at the time of implementation.

It can be seen from the 2012 picture of the seismic code index in Fig. 4 that much work is needed solely on the writing of seismic code indices. Despite the adherence or intention to adhere to the new Eurocodes in Africa and through Asia, many nations still have not signed or enforced codes with respect to seismic resistance.

The current state of the world seismic codes with respect to nonengineered buildings is also a key concern, given the lack of seismic codes for residential buildings and the age of buildings. Many of these buildings are largely vulnerable, use heavy or inappropriate materials, and are not built based on historical earthquake or future

earthquake influences. Bilham (2013) estimates that there are 1–3 billion family homes in this category. However, many societies have learned to build with lightweight materials such as thatch, thus protecting themselves from fatal roof and wall collapses. The age distribution of buildings thus needs to be explored.

Age Distribution of Infrastructure and Its Effect on the Number of Buildings Under Seismic-Resistant Codes

A global building inventory including age and number of stories has been built (Daniell et al. 2011) using census information. The number of possible buildings that were built under some form of code was then reduced, as there are codes where not all building typologies are included under the seismic-resistant codes. The age of buildings has also been used to give a comparison as to the influence of a seismic code on the vulnerable percentage of buildings.

By using the same census data and methodology, the age distribution of infrastructure was collected, with the average shown in Fig. 5.

Global View of Seismic Code and Building Practice Factors,

Fig. 5 Average year of construction for the 244 nations worldwide using census data

G

In countries such as Australia, the average age of infrastructure has stayed fairly constant at around 18 years from 1950 to 2005 (ABS 1995–1996), with a dip toward 1971 as building increased, and is now currently at about 18 years. In terms of the average lifetime of a building, this value is quoted as approximately 75 years. By comparison, this value is around 30 years in China but in Great Britain is around 132 years. For European buildings, a study named “Housing Statistics in the European Union” used census data and studies in order to examine the age of buildings (EUROSTAT 2013). The large difference in the design life of structures leads to an interesting problem when filling in the remaining countries.

If there is not enough new investment in buildings, structures, and infrastructure, the average age of buildings will increase, if there is no new population. As an example, Germany has had very low population growth since 1991. The age of their infrastructure increased from 23.7 years to 26.9 years in 2009. Their general government buildings increased from 22.1 to 28.4 years as compared to dwellings from 25.1 to 27.8 years. Figure 6 shows the average building year in each country as a result of the analysis.

Figure 7 depicts the locations in the world that should be under seismic code as per GSHAP (1999)-derived intensity exceedances for

475 years globally (Giardini 1999). Different intensity-PGA relations were used in Fig. 7 to convert PGA to MMI depending on the location worldwide. It can be seen that most nations should thus have some form of seismic code, and when looking at longer return periods, even more of the globe can be exposed to damaging earthquake intensities.

The percentage of structures in each country under seismic code differs greatly when only the age percentage of structures is only looked at; however, there are usually clauses that buildings of one or two stories are not built to the earthquake code. By using household size and building counts globally, a percentage of buildings built under code has been estimated. The age of structures in each country is integrated against the seismic code index in order to create a percentage of structures that are definitely not built under code. This is, of course, assuming that the age percentage of the buildings is the same over the whole country, which is a reasonable assumption as the natural weighting is toward greater building in cities, which is represented by the entire country values.

The locations of seismic code zonation were then split from the non-code zones by calculating the percentage of buildings in these zones. It should be noted that as a proxy, the $MMI > 6$

Global View of Seismic Code and Building Practice Factors, Fig. 6 The average building year in each country

Global View of Seismic Code and Building Practice Factors, Fig. 7 The locations in the world that should be under seismic code as per GSHAP-derived intensity

exceedances for 475 years globally. Different intensity-PGA relations were used to convert PGA to MMI, depending on the location worldwide

contour was used from GSHAP, as the seismic zone maps collected have not yet been digitized. However, these maps were looked at to check the assumptions, with major changes being made in Italy (where historical codes have not covered the whole of Italy) and China.

Unfortunately, every building type is not covered by earthquake-resistant codes. The next provision that is examined is that of small buildings or those not covered under code. In order to

calculate this value, the individual building codes were looked at. It is difficult to make an assessment in some respects as to small buildings (residential 1–2 stories, or other forms) as, although these are included in some codes, there are many exemptions. The Chinese code (PRC 2001/2008/2010), for instance, uses intensity zones and story heights. Most rural housing is only 1 story and is thus not covered under earthquake-resistant codes. In addition, many

Global View of Seismic Code and Building Practice Factors, Fig. 8 The percentage of buildings in each country that should have been built under a seismic-resistant code (without small building provision)

G

urban buildings under 4 stories in the intensity zone 6 and 3 stories in the intensity zone 7 do not need tie columns for brick buildings. There is an exception for 1-story public buildings, which need to be built under code (2001 code, Chaps. 7 and 10). In Australia, all structures are included; (Standards Australia (1979, 1993, 2007)) however, for domestic buildings less than 3 stories, which are ductile, no provision is required. This code, being an objective-based code, also provides a good basis for engineers to check that the code is being adhered to. An approximate percentage of buildings coming under the provisions have been recorded. In addition, the number of informal and rural buildings is also taken into account.

Existing buildings are also included in some seismic-resistant codes in terms of requiring retrofitting, such as in Argentina, Italy, EC8 (European Union), the USA, Korea, Mexico, New Zealand, Nicaragua, and Venezuela; however, it is unsure as to what extent this has been enforced currently and thus has not been included.

By combining the age of structures which could have a seismic code and the number of nonengineered structures not built to code structures in those zones, a relative percentage of buildings in earthquake zones coming under code can be established. It should be noted that through Central Asia many buildings, although

built to former Soviet codes, have become dilapidated and thus also should be retrofitted or rebuilt.

In general, those countries which have high percentages in Fig. 8 are smaller countries with most of their building stock built in the last 30 years. Marked differences occur across nations with different zonations and building ages across nations not described by such diagrams.

Seismic Code Provisions: Germany

An example is presented below for Germany, in order to show the analysis procedure. The DIN4149 was first implemented in Germany in 1981 after the 1978 Albstadt earthquake. The update to this was given in 2005. Before this, a few other codes had been applied on regional levels, without any federal application (Abrahamczyk et al. 2005). The German code has five zones (no zone, 0, 1, 2, and 3).

Only 31 % of Germany's building stock has been produced after 1981. The code actually applied in zones 1–3 in terms of earthquake loss is for very little of the building stock (15.3 %). This means that under 5 % of possible buildings have been built under some form of earthquake-resistant code. In DIN4149, not every building needs to have had the code change applied, due to the premise of the number of stories (Table 2);

Global View of Seismic Code and Building Practice Factors, Table 2 Various limits on the requirements not to adhere to earthquake codes in zones 1–3

Earthquake zone	Importance class	Maximum story height
1	I–III	4
2	I–II	3
3	I–II	2

thus, even less than 5 % of buildings are applicable to this code. State enforcement ratification of codes is necessary in order for the DIN4149 to be used. The 2005 version has been ratified by most states; however, the new Eurocodes have only currently (as of mid-2013) been ratified by Baden-Württemberg, a state in the southwest of Germany (European Union 2006).

In zone 1, 89 % of buildings do not need to be built to code. In zone 2, around 75 % of buildings do not need to be built to code and in zone 3 around 48 %. This means that less than 0.9 % of buildings in Germany are built to a seismic-resistant code. When focusing on the population and value of the 0.9 % of buildings, this increases to approximately 3 % of capital stock, given the multi-story buildings, infrastructure, and important buildings in importance classes 3 and 4 protected by the earthquake code (hospitals, schools, industrial facilities, etc.). However, a more important problem is posed by the existing hazard, building typology, and standard building code. This formulates a similarly bleak engineered view of the world in terms of loss functions, which presents an additional difficulty in applying a single building approach.

Building Practice Versus Code Compliance

Just because a country has a seismic code in law, this does not mean that the seismic code will be enforced. Thus, building practice plays a major role in earthquake-resistant building, and not only the quality of the seismic code is important but its enforcement, adherence, and lack of corruption in the building. If a building was designed

with a high-quality code, yet the builders were not made to adhere to that code and used substandard materials, then the building would likely not stand up to the earthquake forces.

Corruption has been identified as a key component of earthquake losses, first through the Bilham and Hough (2006) paper in India and then Ambraseys and Bilham (2011) and Bilham (2013) exploring the Transparency International corruption index with respect to earthquakes. There is no doubt that engineered constructions have increased the quality of building against earthquake forces, but much of this has to do with the education of the individuals of that country. Education can be used as a proxy for the quality of understanding of building practice as well as the quality of the mathematics, engineering, and drawings that govern building construction. A study looking at the number of universities offering earthquake-related subjects is another proxy that has been previously used (Santa-Ana et al. 2012). Building error and mistakes increase with lack of education.

Summary

Seismic-resistant design codes have been implemented in many nations around the world over the past century. A summary has been provided as to their current application and to the extent of their use. Although many countries have implemented a seismic-resistant building code, the current percentage of buildings covered by these codes is generally less than 50 % of the building stock.

The enforcement and implementation of seismic-resistant codes is important as even though a country may have a very high-quality code, if it is not implemented or enforced by the government, the code is useless. Given the exponential rise in the number of seismic-resistant codes and the quality of these codes, it can be seen that more work is needed in implementing seismic-resistant codes for existing buildings and assessing residual risk, and care must be taken when referring to the use of codes without looking at exclusion clauses.

Department of Civil Engineering, Tsinghua University, Beijing, People's Republic of China

Synonyms

Earthquake engineering; GPU (Graphics Processing Unit); Massive parallel computing; Seismic damages simulation

Overview

The Graphics Processing Unit (GPU) located in the display card of a computer was originally designed for graphics display. Due to advances in massive parallel computing capacity, the current applications of GPUs have grown far beyond the graphics field.

General-Purpose computation on Graphics Processing Units (GPGPU) was proposed as early as the 1990s. However, such technology was not widely applied for general-purpose computation because, at the time, the application of GPGPU required a graphics application programming interface (API) (e.g., DirectX, OpenGL), which became a barrier to effective coding in general-purpose computation. In addition, many other difficulties have existed for GPGPU with respect to hardware, such as the exchange of data between the GPU and CPU. In 2006, the GPU G80 and the corresponding Compute Unified Device Architecture (CUDA) programming model were released by the NVIDIA Corporation (NVIDIA 2013), which was the first unified shader architecture and solved many of the GPGPU software and hardware problems. Since that time, GPU technology has been widely used in many fields, including many applications in earthquake engineering

involving seismic wave propagation and seismic damage prediction.

GPU Technology

Hardware Platform for GPU Computing

The term “GPU” was introduced by NVIDIA in 1999 with the release of GeForce 256, which is known as “the world’s first ‘GPU’”. Subsequently, ATI Technologies (acquired by AMD in 2006) introduced the visual processing unit (VPU) in 2002, which is not essentially different from a GPU. In 2006, the GeForce 8 series and Compute Unified Device Architecture (CUDA) were introduced by NVIDIA and constituted the earliest and subsequently most widely adopted programming model for GPU computing. In response, GPU hardware had undergone rapid development. Since 2006, the development history of the architectures for the two major types of GPUs may be depicted as follows:

NVIDIA GPUs: G80 (Nov. 2006) – GT200 (Jun. 2008) – Fermi (GF100/GF110, Mar. 2010/Nov. 2010) – Kepler (Mar. 2012).

ATI/AMD GPUs: R600 (May 2007) – RV770 (Jul. 2008) – RV870 (Sep. 2009) – Cayman (Dec. 2010) – Tahiti (Jan. 2012).

At present, Intel, NVIDIA, and AMD/ATI are the market share leaders. Although over half of the market share is owned by Intel, most of the GPUs from Intel are Intel’s integrated graphics solutions, the performance of which is not as high as that of the GPUs introduced by the other two companies. Excluding these integrated GPUs, NVIDIA and AMD/ATI control over 95 % of the market. In addition, there are other companies that produce GPUs, such as VIA Technologies and Matrox.

The reason behind the discrepancy that exists in floating-point capability between the CPU and the GPU is that the GPU is specialized for compute-intensive, highly parallel computation and therefore designed in such a manner that more transistors are devoted to data processing rather than data caching and flow control

Graphics Processing Unit (GPU) Technology in Earthquake Engineering, Application of,

Fig. 1 Comparison between the CPU architecture and the GPU architecture

(NVIDIA 2013), as schematically illustrated in Fig. 1. It is obvious that the GPU has much more cores than the CPU, as shown in Fig. 1, so the GPU is well suited to problems that can be expressed as data-parallel computations with a high level of arithmetic intensity (i.e., the ratio of the demand of arithmetic operations to memory operations).

Software Platform for GPU Computing

Currently, CUDA is the most widely used software platform for GPU computing around the world (NVIDIA 2013). In addition, the Stream platforms of AMD, OpenCL, and DirectCompute are also important GPU computing platforms.

CUDA is a software environment that allows developers to use C as a high-level programming language. Other languages, application programming interfaces or directive-based approaches are also supported, such as FORTRAN, DirectCompute, and OpenACC.

CUDA is carried out by means of a hybrid computing architecture that includes a GPU and CPU. The CPU is responsible for the sequential and logical tasks, and the GPU is used to implement the massive parallel computing tasks. A typical flow chart for a CUDA program is illustrated as follows. First, data are copied from the main memory to the GPU memory. Next, the CPU instructs the main processing and the GPU executes in parallel in each core. Finally, the result is copied from the GPU memory to the main memory.

Two cases of applications of the CUDA program from the CUDA C Programming Guide (NVIDIA 2013) are provided herein to present the CUDA platform in detail.

Example 1: Vector Addition CUDA C extends C by allowing the programmer to define C functions, called *kernels*, that, when called, are executed N times in parallel by N different CUDA threads, as opposed to only once like regular C functions.

A kernel is defined using the `__global__` declaration specifier and the number of CUDA threads that execute that kernel for a given kernel call is specified using a new `<<<...>>>` execution configuration syntax. Each thread that executes the kernel is given a unique thread ID that is accessible within the kernel through the built-in `threadIdx` variable.

As an illustration, the following sample code adds the two vectors A and B of size N and stores the result into vector C :

```
// Kernel definition
__global__ void VecAdd(float* A,
float* B, float* C)
{
    int i = threadIdx.x;
    C[i] = A[i] + B[i];
}
int main()
{
    ...
    // Kernel invocation with
    N threads
    VecAdd<<<1, N>>>>(A, B, C);
}
```

Example 2: Matrix Addition The following code adds two matrices, A and B of size $N \times N$, and stores the result into matrix C :

```
// Kernel definition
```

```

__global__ void MatAdd(float A
[N] [N], float B[N] [N], float C
[N] [N])
{
int i = threadIdx.x;
int j = threadIdx.y;
C[i] [j] = A[i] [j] + B[i] [j];
}
int main()
{
...
// Kernel invocation with one
block of N * N * 1 threads
int numBlocks = 1;
dim3 threadsPerBlock(N, N);
MatAdd<<<numBlocks,
threadsPerBlock>>>
(A, B, C);
}

```

For convenience, *threadIdx* is a three-component vector, by which threads can be identified using a one-dimensional, two-dimensional, or three-dimensional thread index, thus forming a one-dimensional, two-dimensional, or three-dimensional thread block. This provides an easy means to invoke computation across the elements in a domain, such as a vector, matrix, or volume.

The index of a thread and its thread ID are related to each other in a straightforward way: For a one-dimensional block, they are the same; for a two-dimensional block of size (D_x , D_y), the thread ID of a thread of index (x , y) is ($x + y D_x$); for a three-dimensional block of size (D_x , D_y , D_z), the thread ID of a thread of index (x , y , z) is ($x + y D_x + z D_x D_y$).

Earthquake Engineering Applications

Simulation of Ground Motion

The propagation and attenuation of a seismic wave is an important issue in earthquake engineering. Abdelkhalek et al. (2012) adopted a GPU to solve the problem of seismic wave propagation. Considering both the 2D and 3D cases, this group used the GPU Tesla S1070 to perform an analysis of a seismic wave based on a finite

difference approach, obtaining an increased speed of ten times for reverse time migration and up to 30 times for a sequential simulation of seismic waves. Komatitsch et al. (2009) implemented a higher-order finite element application of seismic wave propagation based on two types of GPUs, the NVIDIA GeForce 8800 GTX and the GTX 280, and the acceleration ratios reached 15 and 25, respectively.

Okamoto et al. (2011) used the Japanese TSUBAME-1.2, supercomputer to implement a finite-difference-based simulation of seismic wave propagation. In this simulation, the computing efficiency of a single GPU (Tesla S1070s) reached 56 GFLOPS, which is 45 times the efficiency of a CPU (Intel Core i7). Unat et al. (2012) accelerated a 3D finite difference earthquake simulation with a C-to-CUDA Translator. Running on the Tesla C2050, their program was faster than a highly tuned message passing interface (MPI) implementation running on 32 Nehalem cores. Similarly, Zhou et al. (2012) designed 3D finite difference seismic wave propagation code based on the latest GPU Fermi chipset that implemented the asymmetric 3D stencil on Fermi in order to make the best use of the GPU on-chip memory and achieved aggressive parallel efficiency. The benchmark test on an NVIDIA Tesla M2090 demonstrated that a speedup factor of 10 was achieved compared with the original fully optimized AWP-ODC FORTRAN MPI code running on a single Intel Nehalem 2.4 GHz CPU socket (4 cores/CPU), and a speedup factor of 15 was achieved compared with the same MPI code running on a single AMD Istanbul 2.6 GHz CPU socket (6 cores/CPU). The sustained single-GPU performance of 143.8 GFLOPS in single precision mode was benchmarked for the test case of a $128 \times 128 \times 960$ sized mesh.

Structural Numerical Analysis

The GPU has been applied to structural numerical analysis. The finite element method is an important structural numerical analysis approach. In the elastic structural analysis based on finite element method, most of the computing time is spent on solving matrices. Many matrix computations are well suited to GPU computing. For

example, matrix multiplication can be easily processed by a GPU due to its natural parallel characteristics. Ryoo (2008) conducted a similar test for matrix multiplication with a program that attained an efficiency of 91 GFLOPS on the GPU of a GeForce 8800 GTX. Similarly, matrix decomposition, which is the foundation for solving a linear equation, can also be easily accelerated using a GPU. Volkov and Demmel (2008) optimized a matrix decomposition algorithm on the GeForce 8800 platform, and the decomposition efficiencies of the LU, QR and Cholesky methods were all greater than 180 GFLOPS.

Furthermore, Liu et al. (2008) proposed a general finite element method solution that enables dynamically fast simulation of deformation on the newly available GPU hardware with CUDA. Their test results indicate that the GPU with CUDA enables an increase speed of approximately four times for FEM deformation computation on an Intel(R) Core 2 Quad 2.0 GHz machine with GeForce 8800 GTX. Many commercial finite element analysis codes, e.g., ABAQUS, MSC. MARC, and ANSYS, have released their own GPU-based versions. The performance studies demonstrate that the GPU results in speedups in the range of 3–6 times.

In addition to the finite element simulation, other structural numerical simulations also can be greatly accelerated by the use of GPUs. For example, Durand et al. (2012) simulated rock impact on a concrete slab using the discrete element method (DEM), and the use of a GPU (Tesla C2050) reportedly showed a speedup factor of 30.

Earthquake Detection

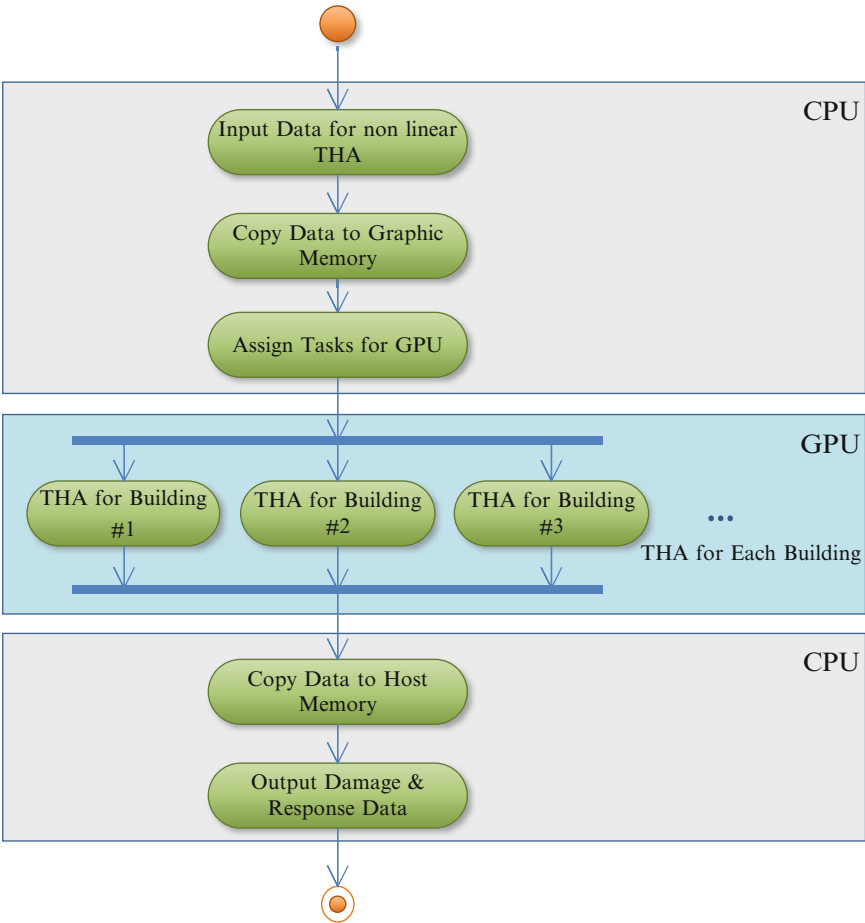

Meng et al. (2012) proposed a GPU-based computation method to accelerate the detection algorithm for earthquakes during intensive after-shocks or swarm sequences. This group applied parallel code to search the Salton Sea geothermal field for missing earthquakes in a 90-day time window around the occurrence time of the 2010 Mw7.2 El Mayor-Cucapah Earthquake. By dividing the procedure into several routines and processing them in parallel, this group achieved an approximate 40 speedup for one NVIDIA GPU card compared with the sequential CPU code.

Repeating earthquakes are occurring on the similar asperity at the plate boundary. These earthquakes have an important property; the seismic waveforms observed at the identical observation site are very similar regardless of their occurrence time. Kawakami et al. (2013) proposed a high-speed digital signal processing method for the detection of repeating earthquakes using GPGPU-acceleration. They compared the execution time between GPU (NVIDIA GeForce GTX 580) and CPU (Intel Core i7 960) processing. In the case of a band-limited phase only correlation, the obtained results indicate that a single GPU is approximately 8.0 times faster than a 4-core CPU (auto-optimization with OpenMP). In the case of the coherence function using three components, the GPU is 12.7 times as fast as the CPU. This study examines the high-speed signal processing of a huge amount of seismic data using the GPU architecture. It was found that the GPGPU-based acceleration for the temporal signal processing is very useful. In the future, multi-GPU computing will be employed to expand the GPGPU-based high-speed signal processing framework for the detection of repeating earthquakes in the future.

The Visualization of Seismic Data

The GPU can also be used for the high-performance visualization of earthquake data. Hsieh and Yang (2011) presented a method using volume rendering based on a GPU to visualize the spectral information of the 1999 Chi-Chi earthquake and the GPU-based volume-rendering system achieved a rendering speed of 30 frames per second (FPS). Xie et al. (2010) proposed a parallel visualization technique for large seismic datasets based on a GPU and CPU cooperation platform. Their experimental results showed that the method exhibited effective real-time performance for a notably large amount of seismic data (10 GB) on standard PC hardware.

Chen and Hsieh (2012) proposed a GPU-based method using volume rendering to better understand and analyze time-varying earthquake ground-motion data, including acceleration, velocity and displacement. This group used CUDA to implement volume rendering (ray

Graphics Processing Unit (GPU) Technology in Earthquake Engineering, Application of, Fig. 2 Flow chart of the seismic damage analysis using GPU

casting), numerical integration (trapezoidal quadrature) and numerical differentiation (centered finite difference), and achieved a speedup of approximately $100\times$ versus a CPU.

Seismic Damage Prediction

Although thousands of buildings may exist in an urban area, if each building is treated as a subtask and a proper computing model is adopted, the computing workload of each subtask is sufficiently small that it can be performed on a single GPU core. Furthermore, there is little interaction between different buildings during an earthquake, which results in there being little data exchange between different GPU cores. Because there are hundreds of cores in a GPU and each GPU core

can be used for the simulation of one building, only a few task assignment rounds are required to complete the simulation of a city with thousands of buildings using GPU computing. Thus, the computational efficiency is expected to be notably high.

A novel solution proposed by Han et al. (2012) used a GPU to accelerate urban seismic damage prediction based on refined building models and nonlinear time-history analysis (THA). Figure 2 shows the flow chart of the Han’s program in which the CPU reads the data, copies the data into the GPU, and assigns the computational tasks to each GPU core, whereas the GPU implements the nonlinear THA for individual buildings and copies the results back to the host memory for output.

Graphics Processing Unit (GPU) Technology in Earthquake Engineering, Application of,
Fig. 3 Benchmark for the CPU and GPU/CPU cooperative programs

Graphics Processing Unit (GPU) Technology in Earthquake Engineering, Application of,
Fig. 4 Partial view of the damage states of each story

In the work of Han, a benchmark case of 1,024 buildings was investigated to validate the efficiency of seismic damage analysis based on GPU. The well-known El Centro record was selected as the ground motion for the benchmark. The peak ground acceleration (PGA) normalized to 200 cm/s².

Two hardware platforms with the same performance-to-price ratio were adopted, as follows:

CPU platform

Hardware: A 2.93-GHz Intel Core i3 530 processor with 4 GB of 1,333-MHz DDR3 RAM.

Compiler: Microsoft Visual C++ 2008 SP1.

GPU/CPU cooperative platform

Hardware: A 2.4-GHz Intel Celeron E3200 CPU and an NVIDIA GeForce GTX 460 with 1 GB of graphics memory.

Compiler: Microsoft Visual C++ 2008 SP1 and CUDA 4.2.

The benchmark cases demonstrated that the GPU/CPU cooperative computation time is approximately 1/39 times the CPU computational time if single precision is used, as shown in Fig. 3. This ratio increases to 1/21 if double precision is used. Seismic damage prediction based on a GPU is shown in Fig. 4, which provides an important reference for earthquake disaster prevention and mitigation.

In summary, existing studies have demonstrated that GPUs provide a highly efficient but low-cost environment for computation and visualization in earthquake engineering. Therefore, in the future, GPU technology will come to be widely used in earthquake engineering.

Accelerograph; Early seismic recording; Old seismographs; Seismometer; Seismoscope

Introduction

A seismometer is an instrument that detects ground motion and a seismograph is a seismometer together with a recorder that records it (a seismogram). Historical seismometers or ancient seismographs are those instruments developed previous to the design and development of the World-Wide Standardized Seismographic Network (WWSSN, Oliver and Murphy 1971). Other previous studies on this topic used to define old seismographs as those designed up to the very early years of the twentieth century because around those years the main basic features of such instruments were already the same as what our present knowledge recognizes as seismographs with analog recording. But it should be realized that the younger graduates in seismology and related topics rarely have had contact with seismic analog recording. For this

reason, some relevant instruments and topics on seismic recording developed on the first half of the twentieth century will be included here. Seismoscopes (a device that only indicates ground motion) and other devices designed and used previous to the development of seismographs will be also considered in this entry.

The ancient seismoscopes and seismographs will primarily be studied from a chronological point of view, but with specific insight into its relevance from the point of view of innovation, that is, their contribution to the evolution of the technical features and/or capabilities of seismic recording.

It is impossible to describe all the models of instruments developed. Therefore, preference will be given to those instruments showing some new development with respect to previous ones. For the readers more interested in this topic or for more details and primary references on the described instruments, there are the outstanding studies of Dewey and Byerly (1969), Howell (1990), and Ferrari (1992) where more information is available and to which this entry is highly indebted.

Recording Earthquakes

The history of early earthquake recording instruments is not a linear one or of continuous progress. It was clear from old times that earthquakes involved ground motion and, thus, recording the ground motion was an important issue to get

some insight in the earthquake phenomena. Also it cannot be ignored that rough devices to detect ground motion were known and used through antiquity and medieval times. It is confirmed that such a device was used on the Exeter siege in 1549. It was used to determine the location of enemies digging underground tunnels. The coeval document says: “hearing a noise underground, he takes a pan of water, and by removing it from place to place, came at length to the very spot where the miners were working; which he knew for certain by the shaking of the water in the pan.” But no application of this or other instruments for the recording or study of earthquakes is known from the renaissance up to the eighteenth century.

In fact, theoretical and technical issues were not developed enough at that time to allow the recording of ground motion. For these reasons the history of the development of early instruments for earthquake recording is one of accumulation of empirical knowledge and of trial and error. Only at the end of the nineteenth century were the key issues concerning ground motion recording started to be properly defined and mastered and the technology of instrumental ground motion recording started to progress steadily.

In order to clarify the following discussion, it should be remembered that, from a technical point of view, two main components can be identified in a ground motion recording instrument. The first is the transducer; this is a device that transforms ground shaking into some other variable (e.g., a voltage) that can be recorded. The second one is the recording system itself, a device allowing to visualize and to store the output of the transducer for further inspection and analysis. The third item is a signal-amplifying and preprocessing system or, in other words, a signal-conditioning system. But this was not a key issue in the early development of seismographs.

In the following sections a review will be made on the evolution of seismic recording up to the middle of the twentieth century. As it is impossible to describe all types of seismographs, the description will concentrate on the instruments that defined new characteristics or new evolution in the recording concepts. Instruments

not described here will be similar to the ones covered here.

An Overview of Seismic Recording

To better understand the descriptions of seismic instruments, some basic theoretical aspects will be described here. For more details, see e.g., Wielandt 2009 or Havskov and Alguacil 2010.

The Nature of Seismic Ground Motion

Earthquakes release energy as elastic waves. The frequency content of the generated waves depends on the size (total energy) released at the earthquake source. Larger earthquakes generate larger amplitudes at lower frequencies relative to small earthquakes. Attenuation of elastic waves propagating on Earth is larger for higher frequencies. Thus, with equal amplitude, lower-frequency waves propagate to longer distances than higher-frequency waves.

For these reasons seismographs adapted to record lower frequencies (<0.1 Hz) are needed to record large and distant earthquakes while instruments with larger amplification at higher frequencies (>1 Hz) are needed to record near, small earthquakes.

From Ground Motion to Seismic Recording

As it will be seen in the following sections, the most widely used principle for seismic recording is the inertia principle.

A device of such type, a mechanical sensor, has a mass with one degree of freedom coupled to a frame (the ground) through a linear restoring force (see Fig. 1). This can be achieved with a spring with restoring force k . A sensor will also have friction which will damp the swinging system. The equation of motion of this system can then be expressed as (Havskov and Alguacil 2010, p. 15)

$$\ddot{z} + 2h\omega_0\dot{z} + \omega_0^2 z = -\ddot{u},$$

where u is the ground displacement (the displacement of the frame); z the relative displacement between the frame and the mass and $\omega_0 = \sqrt{k/m}$,

Historical Seismometer, Fig. 1 Schematic illustration of the most simple seismometer, the inertial mechanical seismometer. A mass is held on a spiral spring. The spring connects the mass with the ground and introduces a linear restoring force. The motion of the mass is damped using

a “dash pot” so that the mass will not swing excessively near the resonance frequency of the system. A ruler is mounted on the side to measure the motion of the mass relative to the ground (From Havskov and Alguacil 2010)

H

with $\omega_0 = 2\pi/T_0$; and T_0 is the sensor's natural period. The damping constant is h and it controls how much the system swings. For $h = 1$ (critical damping) there will be no overswing if the mass gets a push (see Fig. 2).

Thus, just two parameters are involved in the solution of the equation, the natural period T_0 and the damping h . If the system is submitted to a sinusoidal ground motion, the equation has an analytical solution, and the ratio between the mass displacement and ground displacement (amplitude response curve for displacement) is (Havskov and Alguacil 2010, p. 16)

$$A(\omega) = \frac{\omega^2}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4h^2\omega^2\omega_0^2}}$$

From this equation it is seen that for high frequencies $A(\omega) = 1$, so the sensor will measure pure displacement, and $A(\omega)$ diminishes rapidly for lower frequencies, as represented in Fig. 3a. Thus, it is possible to obtain a record (z) reproducing the amplitudes of the ground motion using a sensor with a natural frequency lower than the expected frequencies of the ground motion.

For low frequencies, $A(\omega) = \omega^2/\omega_0^2$ which is proportional to acceleration. Thus, the recording for frequencies lower than the sensor's natural

Historical Seismometer, Fig. 2 The amplitude response function $A(\omega)$ for a seismometer with a natural frequency of 1 Hz. Curves for various level of damping h are shown (From Havskov and Alguacil 2010)

frequency is directly related to the ground motion acceleration (Fig. 3c).

Such principle can be easily applied to the record of vertical and horizontal ground motion. The simplest sensor for vertical motion consists in a mass suspended by a spring (Fig. 1). However, getting a natural frequency of 0.1 Hz would require an unrealistic soft spring combined with a large mass so some tricks are needed; see below. In the case of horizontal motion, it is possible to avoid a spring by using gravity acceleration as the restoring force. The simplest way is

Historical Seismometer,

Fig. 3 Response curves of a mechanical seismometer and electromagnetic seismometer with respect to different kinds of input signals: (a) displacement, (b) velocity, and (c) acceleration. The normalized frequency is the signal frequency divided by the natural frequency (corner frequency) of the seismometer. Plots are in bi-logarithmic scale (From Wielandt 2009, Fig. 5.6)

to use a common pendulum (Fig. 4a). In this case $\omega_0 = \sqrt{g/L}$, where g is the gravity acceleration and L the length of the pendulum. A problem arises when long periods are required since this would require a very large L . For a frequency of 0.1 Hz, $L = 25$ m, not very practical. This problem can be solved using the “garden-gate” sensor (Fig. 4b). In this case $\omega_0 = \sqrt{g \sin \alpha / L}$. Theoretically any period can be reached with such a configuration, but in practice, due to friction, it is hard to get a frequency lower than 0.03 Hz.

Electromagnetic sensors were introduced early in the twentieth century (Fig. 5). The output voltage of such a sensor is proportional to ground velocity for frequencies higher than the natural frequency (Fig. 3b). But good voltage recorders for electromagnetic sensors were not available

until the second half of the century. Early electromagnetic sensors were connected to galvanometers which record the output current generated by the sensor. Galvanometers have a natural period and damping as sensors so the whole response of the electromagnetic sensor-galvanometer is the result of combining both elements (see Fig. 6).

Seismoscopes: The First Known Instrument

The first known devices used to detect ground motion are not seismographs but seismoscopes. These devices make it possible to observe ground shaking, but they do not give a time history of the

Historical Seismometer, Fig. 4 Schematic illustrations of (a) a common pendulum and (b) a tilted “garden gate.” For a free period of 20 s, the common pendulum must be 100 m long. The tilt angle α of a garden-gate pendulum with the same free period and a length of 30 cm is about 0.2° . The longer the period is made, the less stable it will be under the influence of small tilt changes (Adapted from Wielandt 2009, Fig. 5.8)

Historical Seismometer, Fig. 5 Schematic illustration of an electromagnetic seismograph, in which the mass is coupled to an electromagnetic transducer. $u(t)$ represents the ground motion and $z(t)$ the relative motion of the mass with respect to the frame. Motion of the coil attached to the mass through the magnetic field generates an electric current (Adapted from Stein and Wyssession 2003)

Historical Seismometer, Fig. 6 Schematic illustration of the amplitude responses of the components of an electromagnetic seismograph system using a galvanometer. ω_s represents the sensor’s natural frequency and ω_g the galvanometer’s natural frequency. The response of the electromagnetic sensor can be decomposed with the response of the mechanical sensor (a) and the response of the coil (b). The combination of this with the response of the galvanometer (c) gives the overall response of the system (d). All plots are drawn in bi-logarithmic scale (Adapted from Stein and Wyssession 2003)

motion (a seismogram). In its most basic form, they give an indication of ground shaking exceeding a threshold, but they do not give any temporal reference to when it happens or about the real shape of the motion. Others, more sophisticated,

may indicate the direction of shaking, time of the event, or maximum amplitude.

The first known device built specifically for the recording of earthquakes is a seismoscope of Chinese origin. It is acknowledged that it was designed by Zhang Heng (78–139) in 132 A.D (Zhang Heng is the name of the Chinese philosopher as written in the Pinyin transcription system. In many old articles, books, etc., it is found as Chang Hêng or also as Choko and Tyoko, Japanese adaptations of his name). It should be noted that this instrument has not been preserved, and what can be seen in books and museums are recreations produced from the descriptions of the instrument given by Fan Ye and others in the fifth century (Hsiao and Yan 2009).

From the translation of these descriptions given by Dewey and Byerly (1969) and Hsiao and Yan (2009), “The instrument was made of bronze and it resembled a wine jar with a diameter of eight chi (a Chinese measure equivalent to 2 m approx.). Inside, there was a pillar in the center and eight transmitting rods near the pillar. It carried out a switch ball and started the mechanism. On the outside of the vessel there were eight dragon-heads, facing the eight principal directions of the compass. Below each of the dragon-heads was a toad, with its mouth opened toward the dragon. The mouth of each dragon held a ball. At the occurrence of an earthquake, one of the eight dragon-mouths would release a ball into the open mouth of the toad situated below. The direction of the shaking determined which of the dragons released its ball and the instrument made a sound (probably the ball beating the toad) to warn the operator.” See Fig. 7a for a possible reconstruction. It is known that the instrument was operational because there is record of the detection of, at least, a 400-mile distant earthquake which was not felt at the location of the seismoscope (Hsiao and Yan 2009).

The Heng seismoscope is a noteworthy machine in itself. It has a place in the history of technology and it has been studied by many scholars (notice its place in time with respect to Western history realizing that it was built at the time of Roman emperor Hadrian and just half a century after the Vesuvius eruption that

destroyed Pompeii). But it is also noteworthy from the seismological point of view because all studies on its possible detecting mechanism point to the use of the inertia principle, the same that led to the construction of most of the early seismographs. Moreover, it gave an indication not only of the occurrence of an earthquake but also of the direction of the shaking.

Many discussions have taken place about its exact internal mechanism, but a consensus has not been reached. Models with common or inverted pendulums and a model assuming that the oscillating element was the external jar suspended from the pillar have been proposed. Assuming the chronicles are correct, the most puzzling question is that only one ball was delivered and that it pointed in the direction of the epicenter. Thinking on simple mechanisms with pendulums, it looks like more than one ball can be delivered and the pointing direction may be toward or opposite to the epicenter. Anyway, the use of more complex designs, already known at that time, has shown the feasibility of such a mechanism (Fig. 7b–e).

Seismoscopes in Europe: The Eighteenth Century

After Heng’s seismoscope, further references to such instruments disappeared from Eastern literature, and it is necessary to jump in time to the eighteenth century in Europe to find new instruments for earthquake recording. The first mention of such an instrument was written by Jean de Hautefeuille (1647–1724) who, in 1703, proposed a device to detect earthquakes. The background idea was very similar to that of Heng. He suggested to fill a bowl to the brim with mercury, so that the shaking produced by an earthquake would cause some of the liquid to spill out. In order to determine the direction of the shock, the mercury spilling out in each of the eight principal directions of the compass was to be collected in cavities (see Fig. 8 for a sketch of the instrument).

Jean de Hautefeuille was not using the inertia principle. His instrument was designed as an inclinometer because he was assuming that, in

Historical Seismometer, Fig. 7 (a) A possible reconstruction of the outside and inside parts of the Zhang Heng seismoscope. (b) and (c): the position of the eight rods and the detail of one of the rods. (d) and (e): detail showing the

feasibility of a mechanism delivering a ball pointing in the direction of the epicenter due to the compression and dilatation of the incident wave (Adapted from Hsiao and Yan (2009))

Historical Seismometer, Fig. 8 A simple sketch of the seismoscope designed by de Hautefeuille according to Hörnes (1893). A bowl is filled to the brim with mercury so that the shaking produced by an earthquake would cause some of the liquid to spill out. In order to determine the direction of the shock, the mercury spilling out in each of the eight principal directions of the compass is collected in cavities (just the front four are shown)

an earthquake, the ground would be inclined, and the direction in which the mercury spilled would be away from the origin, “where the ground began to be raised.” This is because updated Aristotelian theories about the origin of earthquakes in the eighteenth century suggested underground explosions caused by accumulations of sulfur, bituminous materials, coal, etc., causing dilatation. Thus, this earliest European instrument was expected to detect tilting of the Earth’s surface rather than horizontal displacements. Following the author, it could be possible to get an indication of the distance of the epicenter and the size of the disturbance from the amount of mercury which had sloshed out.

But, as far as it is known, this instrument remained as a design and it was never built.

Anyway, earthquake detection was a “hot topic” at that time, and in the following years a lot of references to seismoscopes are encountered in literature. Design of such instruments became popular among Italian scientists on the eighteenth century, and many devices were designed and developed.

Among them, Nicola Cirillo (1671–1735) is the first confirmed constructor and user of seismoscopes. It was the occasion of the Puglia earthquakes of March 1731 that made him construct the instrument. He used common pendulums of small dimensions (the length of the string was a Neapolitan palm, or 26 cm long approx.). With several instruments installed at different places, he was able to deduce that the amplitude of seismic motion attenuates with distance (Ferrari 1992).

Another instrument at that time worth mentioning is the common pendulum designed by Andrea Bina (1724–1792) in 1751. It is almost certainly the first design of a recording instrument in the history of seismology. According to Bina’s description, a sphere of lead of considerable weight was to be suspended with a rope from a beam on the ceiling to form a long common pendulum (several meters long). In the lower part of the sphere was a needle one and a half inches long penetrating slightly into a layer of sand placed in a wooden box. In the event of a tremor, the needle would leave marks in the sand that, which depending on their form, width, and depth, would have allowed the observer to draw conclusions as to the intensity, direction, and quality of the seismic movement (Ferrari 1992). As it is seen, this instrument could have given indications on the amplitudes and direction of the ground shaking, but without any timing reference. But, as in the case of de Hautefeuille seismoscope, it looks like this instrument was never built.

In 1796, Ascanio Filomarino (1751–1799) described an instrument which he called a seismograph but in fact was a seismoscope. It consisted of a long pendulum attached to a wall whose spherical mass brought down a pencil that, when shaken, marked a trace on a paper of

Historical Seismometer, Fig. 9 The seismoscope by Filomarino according to Ferrari (1990). See detailed description on the text

circular shape (3 in. diameter) placed on a support. In the sphere of iron there were also three bells connected which served as an alarm. Finally, and this is the innovative point, a wire of horsehair blocked the rocker of a clock. When the pendulum swung, the receding hair caused the clock to start, giving an indication on how long ago the earthquake had happened. In this case, the time of the shock is recorded (see a sketch in Fig. 9). It is known that several written records were obtained with this instrument. However, the observations given by Filomarino do not indicate that the timing device was functioning (Dewey and Byerly 1969).

Seismoscopes in the Nineteenth Century

There are references to many more seismoscopes from the middle of the eighteenth century, but it

Historical Seismometer,

 of Forbes (1844). See
 detailed description on
 the text

H

is necessary to wait until the nineteenth century to find the first improved recording device. The most interesting instrument was designed by Scottish James D. Forbes (1809–1868). Due to a series of small earthquakes felt near Comrie, Scotland, a special committee was appointed by the British Association for the Advancement of Science being one of its goals to get instruments to record the shocks. Forbes built an inverted

pendulum (see Fig. 10). Using the same words of Forbes (1844), “a vertical metal-rod *AB*, having a ball of lead *C* moveable upon it, is supported upon a cylindrical steel-wire *D*, which is capable of being made more or less stiff by pinching it at a shorter or greater length by means of the screw *E* [...] The self-registering part of the apparatus [...] consists of a spherical segment *HIK* of copper lined with paper, against which a pencil *L*,

Historical Seismometer, Fig. 11 A sketch of the seismoscope of Mallet. The image of a crosshair in *C* is reflected from the surface of mercury in the basin *B* and viewed through a magnifier, *D* (From Dewey and Byerly 1969)

inserted in the top of the pendulum-rod, is gently pressed by a spiral spring. The marks thus traced on the concave surface indicate at once the direction and maximum extent of the pendulum's vibration."

He used deliberately the inverted pendulum because he knew this was an easy way to obtain long free periods with small dimensions. It is worth pointing out that Forbes was probably the first person to study, from a theoretical point of view and with the aim to calculate its response to ground motion, the effect of an earthquake on a pendulum. But Forbes assumed that an earthquake was just a lateral displacement of the ground with constant speed, and therefore, the results did not give him valuable information about the best settings for his instrument. As Dewey and Byerly (1969) pointed out, Forbes "desired a long period in order that the pendulum remained stationary as the Earth moved beneath it. He clearly wanted to measure ground displacement in an earthquake. However, [...] we can't be sure if Forbes knew that a long-period pendulum would function as a displacement meter for very-short-period oscillations of the ground."

Another interesting point about Forbes pendulum was his deliberate use of "magnification" through the increase of the distance of the writing pencil to the mass. It is the first time a reference to this issue is found. Anyway, the real performance of the instrument was somehow disappointing because it just recorded three of the sixty earthquakes felt. From our present knowledge, it is likely to assume that friction was too high.

During the same years, Robert Mallet (1810–1881), trying to calculate the velocity of seismic waves, used a totally different seismoscope consisting of a mercury container and an eleven-power magnifier. Mallet looked through at the image of a crosshair reflected at the surface of mercury (see Fig. 11). This is a sophisticated version of the "pan" used at the Exeter siege and specifically designed to measure a propagation time, there being no interest in any estimate of the amplitude of the ground motion. In the following years this instrument was to be improved with the addition of photographic recording transforming it into an almost real seismograph without using the inertia principle.

Historical Seismometer, Fig. 12 Seismoscope by Cavalleri. He studied the frequency contents of seismic waves by comparing the amplitudes of oscillation of the different pendulums with different periods (Adapted from Cavalleri 1858)

In Italy, Giovanni M. Cavalleri (1807–1874) designed and built several seismoscopes. Cavalleri constructed an instrument with six short pendulums of different periods, each of which traced the record of its motion in fine powder (Fig. 12). He used them to study the frequency contents of earthquakes and concluded (wrongly) that a range of frequencies from two to four cycles per second would be “sufficient to embrace every undulation occasioned by any earthquake.” Anyway, the Cavalleri studies showed that the ground motion during an earthquake is a composition of oscillatory motions with different frequencies, and it is the first attempt to make this kind of analysis.

It is also around these years that the first devices to record vertical ground motion are made and that electrical circuits are used for the detection of ground motion. The most conspicuous of such instruments was the “Sismografo Elettromagnetico” designed by Luigi Palmieri (1807–1896) in 1856. This instrument, really remarkable at that time, was able to assert time, direction, intensity, and duration of an earthquake. It was not yet a seismograph, as its name may suggest, but a collection of seismoscopes, each intended to record particular parameters of an earthquake (Fig. 13). Palmieri’s instrument seems to have been an effective earthquake detector for local shocks. From the historical records, it looks like it was more sensitive to earthquakes than humans, being the first instrument to clearly attain this goal. Copies of this instrument reached Japan and were in use (and are still preserved) in Tokyo, at least from 1875 to 1885.

It is difficult to describe with words all the complexities of the amplitude indicators and

recorders of this instrument, not the least because the existing copies are different. Of specific interest, the seismoscope for detecting vertical motion consisted of a conical mass hanging on a spiral spring. The mass was suspended just over a basin of mercury. When a slight motion caused the tip of the cone to touch the mercury, an electric circuit was completed, which caused a clock to stop, indicating the time of the shock. Horizontal motion was detected with common pendulums, whose swinging completed the same circuit as that completed by the mass-spring seismoscope. In this case, a circular narrow channel filled with mercury was placed around the bottom of the oscillating mass. It was possible to reduce the distance between the mass at rest and the mercury to tens of millimeter.

These types of seismoscopes had a high sensitivity, and their design was copied in a large number of further starting/stopping devices for recording apparatus as it will be mentioned below.

Already at the end of the century, in 1895, Giovanni Agamennone (1858–1949) introduced his double-action electric seismoscope (Fig. 14). This instrument can be considered as the final synthesis of the Italian know-how on seismoscopes, closing its evolution. It uses the oscillatory character of the earthquake ground motion in an elegant form. Two inverted pendulums of different periods are set aside each other. Their suspensions bars, connected to the poles of a battery, have an electric contact at the top. When at rest, the contact is open through a gap of few tens of a millimeter. Any slight motion of the ground causes the pendulums to oscillate (at different frequencies) and, thus, to complete the electric circuit. A bell rings and a clock, or

Historical Seismometer, Fig. 13 Palmieri seismograph. The spiral spring (*E*) was used to detect vertical motion. Horizontal motions along different axes were detected and recorded electrically by the movement of mercury in the U-tubes (on the *left* side). The closing of

an electric circuit activated electromagnets (*C* and *D*), which caused the clock to be stopped, thus recording the time of the arrival of the seismic waves, and the rotation of the drum (*i*) was started, with paper being unwound and marked at *m* (From Palmieri 1873)

Historical Seismometer, Fig. 14 Agamennone double-action electric seismoscope. Two inverted pendulums, with different free period, are set aside. The close proximity of the two upper extremities of the pendulums had the effect, in the case of a tremor, of making them come into contact with one another, completing an electric circuit (From Ferrari 1992)

any other device, may be started by the electric signal.

The First Seismograph

A fact ignored presently is that by the middle of the nineteenth century, seismoscopes became widely distributed around the world. Its presence and use other than in Italy and the UK is documented in Cincinnati, USA; on the occasion of the New Madrid earthquakes of 1811 and 1812; in Tabriz, Iran, for the October 4, 1856, Persian earthquake; in Manila, Philippines, for the June 20, 1857, event; or in several places in Germany for the June 24, 1877, Herzogenrath earthquake.

But seismoscopes do not give much information about the nature of earthquakes, and this is the most probable cause for the present low relevance of seismoscopic observations. The characteristics of ground shaking during earthquakes continued to be unknown as well as the characteristics of wave propagation at far distances. From our present knowledge about earthquake recording, it is possible to infer that sensors (seismometers) were becoming adequate for their task, but recorders were not. The lack of earthquake recordings (amplitude as a function of time, a seismogram) made it difficult to further study the earthquake phenomena.

But around 1875 Filippo Cecchi (1822–1877) built what it is now considered the first seismograph. However at the time it passed quite unnoticed. Unlike any of the instruments discussed up to this point, the Cecchi seismograph was expected to record the relative motion of a pendulum with respect to the Earth as a function of time. It was based in the inertia principle, and as described by Dewey and Byerly (1969), two common pendulums were used to record horizontal vibrations, each one oscillating in a unique direction and placed perpendicular to each other. Their free period was 1 Hz and the ground motion was magnified three times by a thread-and-pulley apparatus. A mass held on a spiral spring, as shown in Fig. 1, was used for the recording of the vertical motion. A device

designed to record rotary motions was also incorporated into the seismograph. It consisted of a crossbar with weights at both ends, much like a dumbbell, which was pivoted at its center of mass so as to rotate in a horizontal plane. Restoring force was applied to the dumbbell by springs so that it oscillated with a period of one second (Fig. 15). A more detailed description can be found in Ferrari (2006).

The instrument was not designed for continuous recording and Cecchi arranged a seismoscope to start a clock and to put into motion the recording surface, a smoked glass plate, at the time of an earthquake. The recording surface would move under the needles at a speed of one centimeter per second for 20 s. From the time on the clock, an observer arriving at the seismograph would determine how long before his arrival the earthquake had occurred.

It looks like several similar instruments were installed at Italian observatories and, certainly, one in Manila, Philippines, but the first confirmed record of this instrument was on February 23, 1887, at the occasion of the large earthquake that occurred near Nice, France (Fig. 16). This points to an insensitive instrument and explains the reason why such an achievement passed almost unnoticed. Our present interpretation is that the friction of the recording system was too high and, most likely, the starting seismoscope was not sensitive enough.

At the same time, other developments important for the future of seismometry were taking place; among them were experimental and theoretical studies about horizontal pendulums. Researchers needing to detect small gravity variations on laboratory and those working in geodesy studied the properties and behavior of horizontal pendulums (its specific characteristic was the way to hold the oscillating mass, as can be seen in Fig. 20-3) and he also developed the theory of such an instrument. A mirror was attached to the pendulum thereby magnifying its motion using a light beam reflected on it.

Another important theoretical development was done by Perry and Ayrton (1879), both British professors working at Japan. They published a paper entitled *On a neglected Principle that*

Historical Seismometer, Fig. 15 Cecchi

seismograph. Restoration of the original instrument presented at Genoa in 2000. In the front, the two common pendulums are seen. Among them, the elongated box is the place where recording plates were fixed (four plates for the three translation components and the rotational one). The rotational sensor is seen just behind to the right of the common pendulum (Photograph by the author)

may be employed in Earthquake Measurements. In this paper the authors analyzed the motion of damped and undamped mass-spring oscillators subjected to a periodic force. Now the importance of this contribution is clear, but it was almost ignored at the time of publication.

Developments in Japan

In its efforts to modernize the science and technology of the country, Japan hired, in addition to Perry and Ayrton, many foreign professors in the last quarter of the nineteenth century. Among them were John Milne (1849–1913), Alfred Ewing (1855–1935), and Thomas Gray (1850–1908). By living in one of the most earthquake-prone countries of the world, they were encouraged to study how to record earthquakes. The three, with solid engineering

background (Milne served as professor of mining and geology, Ewing of mechanical engineering, and Gray of telegraph Engineering), were in an optimum position to solve the problem of how to record ground motion; however, they were more handicapped by technical problems than by theoretical ones.

Few weeks after the earthquake on February 22, 1880, at Yokohama, and following a proposal by Milne, a seismological society was founded in Japan. Since the three were already involved in earthquake studies and have an engineering background, they gave priority to solving the technical problems of ground motion recording.

They studied different possible types of seismometers and recorders. It is known from their writings that they were looking for instruments with a free period larger than the periods of the signals they wanted to record, taking full advantage of the inertia of pendulums. The first

Historical Seismometer, Fig. 16 Cecchi seismograph record of the 1887 Ligurian earthquake. This record was obtained from one of the glass recording plates attached to one side of the elongated box described in Fig. 15 (From Ferrari 2006)

Historical Seismometer, Fig. 17 Drawing of the Ewing horizontal pendulum (From Ewing 1881)

instrument of their long production, built by Ewing, was a common pendulum of 5 s period (approximately 7 m long) because they thought this period was enough for their goal. A simple lever whose fulcrum was attached to the ground gave a six times magnification and recorded on a continuously revolving, circular smoked glass plate. The motion of the pendulum was resolved into two perpendicular components by the recording apparatus (two perpendicular levers were used). Not properly acknowledged up to now, it should be pointed that the great innovation of this instrument was the recording system, giving a long continuous record, and that it was applied successively to other models.

Almost in parallel Ewing tried recording earthquakes with a horizontal pendulum. His design was really successful, being the first to do so in the field of seismology. With small dimensions, the horizontal Ewing pendulum consisted (see Fig. 17) of a light rigid frame *c* pivoted at points *e* so as to swing like a garden gate around that axis of rotation. The cylindrical mass *a* is pivoted at the axis of percussion of the frame *b*. Again he used the revolving smoked glass and six times magnification. The weight of the oscillating mass was less than one kg.

Both of Ewing's instruments, the common-pendulum and horizontal-pendulum seismographs, recorded a small earthquake on November 3, 1880, giving the first lengthy seismic records of earthquake motion as a function of time. Finally, it was possible to have an idea of

the ground motion during an earthquake, and for the first time, seismologists could design their instruments with some knowledge of the phenomena the instruments were to record.

But an instrument for the vertical motion with a similar long period as those designed for the horizontal ones was still elusive. The solution came when Gray introduced a method of increasing the period of a mass-spring system by attaching the spiral spring to the short arm of a lever and attaching the mass to the long arm of the lever. This increased the period to few seconds by increasing the effective mass of the pendulum bob (see Figs. 20-8 and 9). Thus, even with many drawbacks with respect to our present knowledge (not a damped instrument, large dry frictions), a three-component instrument was now available.

Recording Earthquakes Globally: Teleseismic Recording

Another step was needed for the seismograph to be recognized as the key instrument not only for the study of earthquakes but also for the study of the Earth's interior. This was initiated by Ernst von Rebeur-Paschwitz (1861–1895). His main research area was geodesy and, specifically, the lateral deformations of the Earth's crust. To measure the deformations he built sensitive horizontal pendulums to measure slight changes in the direction of the vertical gravity. On April 17, 1889, two of these instruments, located in Potsdam and Wilhelmshaven, recorded simultaneously an anomalous signal that, from the newspapers information, he related to a large earthquake which had occurred in Japan.

He published a note about this observation in *Nature* that has become one of the milestones of observational seismology (Rebeur-Paschwitz 1889). The accompanying published seismic records have been reproduced many times (here also, see Fig. 18). The main result of his discovery was that, for the first time, the possibility to record distant earthquakes was confirmed. This possibility had already been proposed by others. The observation also confirmed that the whole

Earth is elastic and that therefore elastic wave theory can be used to analyze the behavior of seismic waves. Looking at the record, a curvature on the baseline can be seen. This curvature corresponds to the deformation caused by earth tides. The instrument was a tiltmeter but it recorded earthquakes, as gravimeters do.

The instrument consisted of a heavy base containing, inside, a horizontal pendulum sitting on a rigid frame, rotating around two bearings at the top and the bottom, each consisting of a point pressed into a socket (Figs. 19 and 20-2). He used a photographic recording. It was obtained through a mirror attached to the oscillating frame, which reflected light from a lamp through a cylindrical lens to a rotating drum which was covered with photographic paper. The drum turned 11 mm in an hour. As this system reduces friction significantly, the pendulum was only 10 cm long and carried a mass of only 42 g. It was usually used with free periods from 12 to 17 s and a static magnification of 100 (Dewey and Byerly 1969). A time reference was obtained with a second fixed light trace which wrote on the same photographic paper. Every hour, this second trace was eclipsed for 5 min. The magnification and the free period of Rebeur's pendulum were 20 times bigger than Ewing's pendulum. This instrument can be considered as the first approximation to what was needed to record teleseismic events.

The original instruments were, for many years, assumed lost, but recently original frames and other parts have been found by Fréchet and Rivera (2012).

The Seismograph Evolves

It is possible to identify, in the last quarter of the nineteenth century, three main groups or "schools" of seismograph designers and even to assign nationality to each one: the Italians, with their already long tradition of experimentation, in which Palmieri and Cecchi can be their best heralds; the Anglo-Japanese, with the Milne-Ewing-Gray trio, a rapidly progressing group characterized by its good equilibrium between the

H

Historical Seismometer,

Fig. 20 Different pendulum settings used for earthquake recording. It is possible to establish a seismograph classification according to the mechanical constitution of the transducer: (1) conical or bifilar pendulum, (2) rigid pendulum, (3) Zöllner pendulum, (4) vertical pendulum, (5) torsion pendulum, (6) inverted pendulum, (7) flexure pendulum, (8) vertical oscillator, (9) vertical rotational oscillator (From Batlló 2004)

theoretical and experimental approaches to the topic; and finally, with a really poor experience of earthquakes due to the low seismicity of its country, the Germans, Rebeur-Paschwitz at the front, with a geodetic background and a large experience in detecting very small ground motions at low frequencies.

The approach of each group to the seismic recording problem was almost independent and quite different. But when, within few years, the three arrived to obtain their first valuable records, the information among the different groups traveled fast, and the new technical procedures of one group were really soon implemented by the others.

Although other principles were tested, it is clear that all designers adopted the inertia principle for the design of the main instrument. All kinds of pendulums were tested (see Fig. 20).

Around that time (probably of Italian invention) the classical analog continuous seismic record consisting in a spiral line plotted on a paper placed on a drum was introduced. The lateral translation of a drum was obtained by just substituting its rotational axis with a screw. It was now possible to have a 24 h record on a unique sheet of paper with manageable dimensions.

In 1895, Giuseppe Vicentini (1860–1944) and Giulio Pacher (1867–1900) introduced a new

Historical Seismometer,

Fig. 21 Vicentini seismograph, with horizontal and vertical components as installed in the Alicante Observatory, Spain (Original photograph from the IGN archive)

H

common pendulum specially designed to record near earthquakes. Now it was quite clear that signals of near earthquakes contained higher frequencies than those from teleseismic events. For this reason they designed an instrument optimized for near-earthquake recording. A common pendulum of 100 kg with a free period 2.3 s recorded on smoked paper with a speed of 15 mm/min. The motion of the pendulum was amplified and resolved into perpendicular components by levers. Static magnification was set to 80. The recording was on smoked paper, and following a trend common to Italian instruments at that time, they used large masses to overcome the frictions of the amplifying and inscription mechanisms. The good results obtained made them add a vertical component. It was quite original in design and consisted of a flat spring clamped to a wall from one side and with the oscillating mass (50 kg) at the other end (Fig. 20-7). The free period was 1 s approx. and magnification was 130. The resulting instrument was known as Vicentini seismograph and it was used at many places for near-earthquake recording up to the middle of the twentieth century when it was finally superseded by electromagnetic short-period seismographs (see Fig. 21). The three components were written side by side on the same continuous record.

Milne, on coming back to England, centered his interest on global seismicity. For this objective he used the horizontal pendulum he designed in Japan in 1894 (Fig. 22). In this instrument he adopted the photographic record and, thus, he combined it with a light oscillating mass (less than half kilograms). The free period was set near 16–18 s and magnification was 6–9. He adopted also continuous recording, but did not adopt the laterally translating drum (he did in later versions of the instrument). For this reason the early records were long rolls of photographic paper. Paper speed was just 1 mm/min and one roll of 10 m lasted 1 week. The instrument, thus, was not convenient for immediate analysis of seismograms. Even not being an instrument of outstanding performance, it is really important in the history of seismology because, due to a proposal of Milne, it was selected by the British Association for the Advancement of Science to be deployed around the world (and, effectively, it was) in a first attempt of making a worldwide network.

By the end of the nineteenth century, the British professors in Japan returned to Europe and the Japanese took full responsibility for continuing the outstanding seismological research in Japan. Fusakichi Omori (1868–1923), a collaborator of Milne, continued the design of horizontal

pendulums. He turned to continuous recording on smoked paper and, as needed in this case, heavier masses (10 or more kg). In its most common form, Omori's pendulum consisted of a mass on a rod, pivoting about a socket, with the mass held up by a flexible wire. With a free period of about 20 s, static magnifications about 10–15, and paper speed of 5/10 mm/min, they were rough instruments of easy use and maintenance. These qualities make them popular and were copied

elsewhere. Still in the middle of the twentieth century, they were common in secondary seismic stations. The Bosch factory, in Strasbourg, commercialized a popular version under the name "Bosch-Omori" pendulums (Fig. 23). The worldwide distribution, relatively long period, and adequate paper speed make their records still valuable for the study of large earthquakes which occurred in the early years of the twentieth century (Batlló et al. 2004, 2008).

Wiechert Inverted Pendulum

Emile Wiechert (1861–1928) began his experiments with earthquake recording in 1898, at the just created Institute for Geophysics at the University of Göttingen, with a pendulum with photographic recording and viscous damping. He introduced the damping to lessen the effects of the pendulum's free oscillations and he was the first to introduce such a device in a seismograph. But after a scientific round trip to Italian observatories, he developed already in 1900 a totally new instrument, his worldwide famous astatic pendulum. The new instrument combined characteristics of the instruments already in use in Germany and Italy and some “premiers” to be attributed to Wiechert himself. After some years of experimentation and improvements, Wiechert published it in 1904.

The first “premier” of this instrument was (recovering the idea of Forbes) the use of an inverted pendulum stabilized by springs and free to oscillate in any direction horizontally (Wiechert 1904). In this case the restoring springs were applied to the top of the inertial mass. A joint (of cardan type) at the base of the pendulum permitted motion in any horizontal direction. The 1904 pendulum (Fig. 24) had an oscillating mass M of 1,000 kg. Using such a large mass made it possible to overcome dry frictions. The free period of the pendulum was around 10 s. The relative motion of the mass with respect to the ground was resolved into perpendicular components, magnified 200 times by a mechanical lever system (H , OS , and S), and written on a smoked paper for continuous record P . Paper speed was between 10 and 15 mm/min. Time marks were put on the paper every minute by lifting the writing index off of the paper. The viscous damping was obtained by connecting the motion of the pendulum mass to pistons which fit closely inside cylinders D attached to the seismometer stand. Resistance of the air to the piston motion provided damping for the pendulum; this resistance was controlled by a valve which had the effect of regulating the amount of air space between the piston and the cylinder. The lever system and recording are indebted to Italian technology

Historical Seismometer, Fig. 24 General sketch of the horizontal Wiechert astatic seismograph. See description in the text (From Ferrari 1992)

while the free mass period and high (at that time) amplification reflected German experience and the air damping device was another premier due to Wiechert. The damping device was the most important innovation because its behavior approaches the expected mathematically modeled viscous damping.

Last but not the least, in parallel with the instrument development, Wiechert studied carefully the theory of the motion of pendulums submitted to ground oscillatory motion and as a result he developed the theory of the response of mechanical seismographs to ground motion. The presentation of this problem in actual textbooks is very similar to the description by Wiechert.

Finally, in 1905 a vertical component complemented the astatic horizontal pendulum. Using as much as possible the sound design of the horizontal instrument, the overall resulting instrument was much more conventional, the large mass being held with springs, and it was impossible to obtain a free period larger than 5 s.

The Wiechert astatic instrument became a reference instrument for many years. Several manufacturers commercialized different versions of the instrument, and by the time of the second World War, more than 100 seismic stations around the world were using these kinds of instruments. Several are still in operation used as

Historical Seismometer, Fig. 25 Record of the earthquake that occurred on April 23, 1909, near Lisbon, Portugal, as recorded in the N-S component of the Wiechert

seismograph installed at Munich, Germany, at 2,000 km from the epicenter. P and S waves arrival and surface waves are clearly identified (From Batlló et al. 2008)

reference instruments. Figure 25 shows an example of a typical record obtained with a Wiechert instrument. P and S waves are clearly identified and the record is not different for our present seismograms.

The Electromagnetic Seismograph

Boris B. Galitzin (1862–1916), in charge of the Pulkovo seismic station, was, as Wiechert, deeply interested in the improvement of seismic recording. In 1905 he came with a totally new instrument, the electromagnetic seismograph (Fig. 26). The new seismograph used, instead of mechanical transducers amplifying the ground motion with levers, an electromagnetic transducer. To do so coils attached to the oscillating pendulum were moving through a magnetic field created by permanent magnets. Ground motion was thus converted to an electric current and optically recorded, with the help of a galvanometer, in a photographic paper introducing, thus, a second oscillating element. Viscous damping was obtained magnetically, with a sheet of copper attached to the oscillating mass moving in the magnetic field created by a second pair of magnets. The horizontal pendulums (one

for each component) used the Zöllner suspension (Fig. 20-3) and the vertical instrument used the suspension system introduced by Ewing in Japan (Fig. 20-9). Their masses were few kilograms. Its design allowed to separate the “sensing” device from the “recording” device. From then it is called the seismometer-galvanometer system.

The new instrument was the fruit of careful experimentation but also, as in the case of the Wiechert instrument, a result of theoretical study. The horizontal pendulum’s free period was set around 24 s for the horizontal and 12 s for the vertical components. The galvanometer’s free period was set to the same frequency as the seismometers and both the seismometer and galvanometer had critical damping. It was then possible to get an analytical solution to the equation of motion for the whole coupled system seismometer-galvanometer. The peak magnification was more than one thousand times and a typical paper speed was 30 mm/min. Another advantage was that by using parallel and serial coupled resistances, both the damping and the gain of the instrument could be regulated easily.

The new instrument was much more sensitive than any previous instrument and superior to them in almost all aspects, except complexity of recording and price. At that time photographic

H

recording was not affordable to any seismic station. While a standard mechanical seismograph (if properly damped) has a flat response to displacement for frequencies above the natural frequency, the transfer function of the seismometer-galvanometer system is no longer flat (see Fig. 6) making it a bit more difficult to analyze the seismograms. The available magnets suffered from demagnetization, and thus, the overall magnification of the system changed. For these reasons, their use expanded slowly.

From Teleseisms to Near Earthquakes

Wiechert astatic seismograph and Galitzin's electromagnetic instruments gave a good solution to the recording of teleseisms. They were for many years the standard instruments of the most important seismic stations around the world, complemented at secondary stations with a variety of instruments, many of them horizontal pendulums of the Omori type, as the Mainka pendulums (Fig. 27), with nominal characteristics similar to the Wiechert instruments but of easier maintenance. But overall the quality of the mechanical parts of these cheaper instruments was not as good as those of the original Wiechert (and, as pointed by McComb (1936),

performance of damping oil systems as viscous damping was not satisfactory) lowering the quality of the obtained seismograms.

Nevertheless, the studies on the structure of the Earth progressed fast. But recording of small earthquakes in the near field was still deficient. To get a high amplification at frequencies near 1 Hz and higher was not an easy task. Some solutions were proposed. To improve the mechanical transducers (the main problem was to overcome the friction), large masses were used. Italian designers recognized this problem already at the end of the nineteenth century. Wiechert himself moved this way constructing a short-period Wiechert-type instrument with 17 t. Later, in 1922, the Quervain-Piccard mechanical seismograph was built in Switzerland. A mass of 21 t was "floating" on springs, and separate recording in three directions was obtained by levers. The static magnification was 1,700 and the free period was 3 s for the horizontal components and 1 s for the vertical component.

At the same time a totally different solution was adopted in California. The result was the famous Wood-Anderson instrument (Fig. 28). It takes advantage of a torsion suspension (Fig. 20-5) for the pendulum (Anderson and Wood 1925). A small mass is enough to obtain

Historical Seismometer, Fig. 27 Front view of the Mainka horizontal pendulum. The recording system has been removed to show the oscillating mass and the structure holding it. Mass is held at the top of the structure and at a second point (not seen), just behind the axis at its center, as in the Bosch-Omori instrument (From Batllo 2004)

high gain when, to avoid friction, it is combined with magnetic damping and photographic recording. In this case, the most cumbersome element is the photographic recording. With a mass of less than 1 g, it has a free period of 0.8 s and magnifications larger than 2,000 (the nominal magnification of the commercial instruments was 2,800 even though further studies by Urhammer and Collins 1990 showed it is smaller). Unfortunately, a vertical component was never produced even though its construction does not offer any further technical complication.

Benioff Reluctance Seismometer

Further research of the ways to increase seismometer sensitivity to be able to detect smaller signals got Hugo Benioff (1899–1968) to introduce, in 1930, the variable reluctance seismometer (Benioff 1955). Its principle is similar to the electromagnetic sensor, but instead of a moving coil in a magnetic field, the transducer is of the same type of those used in telephone receivers. A moving magnet supplies flux across two or more air gaps to an armature around which is wound a coil of wire. Changing air gaps, caused by the motion of the magnet due to ground shaking, generates the current in the coils. The device generates much stronger signals than the classical electromagnetic sensor. Using photographic recording it then becomes easy to get amplifications of 100,000 at 1 Hz. Horizontal and vertical seismometers were produced and they became later, almost unmodified, the short-period equipment of the WWSSN (Fig. 29).

The sensitive transducer permitted to use some recording principles previously abandoned because of the lack of adequate technology. This was the case of the strainmeter developed also by Benioff in the 1930s. The strainmeter dismissed the cherished principle of pendulum inertia and measures the variation of distance between two points at the passing of seismic waves. The new variable reluctance transducer could be used to properly measure this distance and thus to use the strainmeter as seismometer.

Strong Motion Measurement

Earthquake engineering and related fields also use instruments that record ground motion. As it is seen in the previous paragraphs, shortly after the first World War, technological leadership, at least in the seismic recording, transferred to the USA. This is also the case for strong motion recording.

Since early times, there was an interest in measuring vibrations of buildings and other constructions, and attempts were made to use seismic instruments for that purpose. It is possible to give

Historical Seismometer, Fig. 28 General sketch of the Wood-Anderson seismometer. A zoom of the oscillating mass is shown in the right part (elements T , C , and m) (From Anderson and Wood 1925)

Historical Seismometer, Fig. 29 WWSSN Benioff variable reluctance seismometer for the horizontal component. The transducer is placed in the central part of the instrument between the two mass disks (Original photograph in the IGN archive)

many examples. Ewing, already in 1888 in the UK, used his double pendulum to measure the vibration of the new Tay Bridge during the passing of railway trains. Guido Alfani (1976–1940), in 1911, with a portable seismograph specially designed for use in buildings, called “trepidometer,” studied the vibration of the famous Pisa inclined tower when bells were ringing. Contemporaries Albin Belar (1864–1939) in Ljubljana and Manuel Sánchez Navarro (1867–1941) in Granada, among others, built also “tromometers” to use them in engineering works. But all of these instruments lacked enough sensibility in the needed range of frequencies to properly analyze the obtained signals (even the frequency contents of those signals were not well defined at that time). Even more, most of them were not damped instruments. As it happened in many other occasions related to the seismic recording, proper ideas already existed many years before its proper realization. It is worth to point out that already in 1915, Galitzin studied the possibility of using the piezoelectric effect to build accelerometers (Fremd 1997), but lacking the electronic technology needed to amplify signals, the device was not feasible at that time.

In the early 1930s several damaging earthquakes in the USA started a discussion about seismic safety, and the engineers realized that real progress in earthquake engineering (an engineering branch not yet defined at that time) passes through detailed knowledge of accelerations in buildings and structures, but there was no instrument capable of doing these measurements. However, theoretical and technological studies were properly developed at that time to describe the problem. So just 2 years passed since the starting of the Strong Motion Program, in 1931, up to the recording of the first accelerograms for the Long Beach earthquake of May 10, 1933.

The appointed committee for the Strong Motion Program was very fast in determining that it was important to record acceleration instead of displacement and also in the interesting range of frequencies and the expected amplitudes ($f < 10$ Hz and amplitude up to 0.5 g) to be

recorded. All this knowledge about expected values was already accumulated from the previously available observations as well as how to use mechanical sensors to record ground acceleration.

Once specifications were defined, a review of available technology was made. The choice was to use a Wood-Anderson torsion pendulum-type seismometer (Trifunac 2009). In this case a vertical component was also built. Problems with the proper set of the delicate suspension (in this case with four wires, as explained by Trifunac 2009) required a change for a more robust pivoted and spring-stabilized system already in 1933. Analog recording on photographic paper forced the choice for a triggered instrument. The triggering seismoscope was still of the Palmieri type. The resulting accelerometer (Fig. 30) had three components with a free period of 10 Hz (to properly record accelerations at lower frequencies). The amplitude of the trace was 4 cm for an acceleration of 0.2 g (remember that it was expected for this instrument to have a flat response to acceleration in the range of interest). The recording speed was 1 cm/s and time marks were introduced each 0.5 s.

The instrument worked quite well but was quite expensive for particulars (an indication of that is that accelerometers were not commercialized before 1963). Thus, and mainly for engineering purposes, well-calibrated seismoscopes continued to be on the first line of earthquake engineering up to the advent of electronic systems and digital recording, in the mid-1970s (Fig. 31).

Summary

The development of the early stages of seismometry and the evolution of the early seismographs and of seismic recording have been presented. Evolution of the instruments, from the first known devices of the second century A.D. up to the devices of the nineteenth century, was slow and with many failures, the main issue being the lack of knowledge of the real ground motion during earthquakes and, thus, of a clear goal.

H

Historical Seismometer, Fig. 31 USCGS seismoscope for strong motion recording. This instrument was designed in the 1950s and continued in use up to the time of the digital accelerograph (From Hudson 1963)

This lack of knowledge was also due to the lack of proper recorders able to record continuously. This was a common problem to all sciences and it was not properly solved until the second part of the nineteenth century. Once the first records were obtained, seismometry progressed much

faster. The tools for the theoretical analysis of seismic recording (mainly Newtonian mechanics) were already available. Electromagnetic theory, useful to develop electromagnetic transducers, was developed at the same time and was soon incorporated to seismometry.

Humans experience near earthquakes (felt earthquakes) and this led to the early attempts of seismic recording. But the large development of seismic networks at the beginning of the twentieth century was mainly made with the purpose of recording teleseisms. Near-field recording was not properly addressed up to the interwar period of the twentieth century. At first specific instruments for the recording of near earthquakes were developed and later, by the demand of engineers, accelerometers were designed and deployed. In the middle of the twentieth century, with the development of the WWSSN and similar instruments (like the Kirnos seismographs), seismic instruments gave results similar to our present instruments. Nevertheless, sophisticated seismoscopes, cheap and easy to handle, were generally deployed in seismic areas up to the advent of new active seismic sensors and digital recording which solved many of the problems of the older instrumentation.

Introduction

The scope of this entry is to introduce hyperspectral remote sensing data and its applications in urban environment.

In the last decades imaging spectroscopy (Goetz et al. 1985), commonly referred to as hyperspectral remote sensing, has become a widely used method for identification and quantification of surface materials in different kinds of environments, such as urban, rural, and geological areas (Heiden et al. 2012).

A hyperspectral sensor is able to record a high number of spectral bands, corresponding to narrow contiguous wavelength intervals. This characteristic permits the discrimination of different materials based on their unique spectral characteristics, called spectral signature. In general, two materials can be distinguished by broad and narrow spectral reflectance features determined by

the chemical composition of the materials. However, some materials may present strong spectral similarities except for a narrow part of the spectrum. From this point of view, hyperspectral sensors have the ability to detect more materials than multispectral sensors.

In the literature, several studies have analyzed the spectral characteristics of material detected by hyperspectral instruments, usually by means of laboratory and field spectroscopic investigations (Ben-Dor 2001).

Hyperspectral remote sensing demonstrated its effectiveness in several fields of application, such as precision agriculture, security surveillance, physics and astronomy, environmental analysis, and mineralogy, as well as in hazard monitoring and management.

In urban environment, hyperspectral remote sensing can be extremely useful, in particular for the management of pre-/post-seismic events. In this optic, the ability of hyperspectral sensors to discriminate several materials can be extremely useful in the characterization of the building type, by identifying the material used for the construction. Another important use of hyperspectral imaging is the ability to produce accurate geological maps of the soil.

Hyperspectral images provide a great amount of spectral information, however, when compared with multispectral images, the main limitation of this kind of data resides in their dimensionality. Since hyperspectral data cubes are large, their dimension may have a negative impact in terms of computational processing load and also on the storage. The dimensionality problem limited also a proper development of satellite-based hyperspectral systems, since transmission and storage of acquired data become extremely difficult. From this point of view, reducing the dimensionality of hyperspectral images is one of the most important processes for the exploitation of the information provided by hyperspectral.

In the following paragraphs, different aspects of hyperspectral imaging in urban area, with a particular attention to those related to seismic events, will be addressed.

Hyperspectral Image Overview

$$O = I \otimes R$$

Hyperspectral Sensors

Both scientists and common people are becoming increasingly concerned with environmental phenomena such as the photosynthetic conditions of the vegetation, wide deforestation and fires, desertification, sea pollution, and hazard monitoring, together with the general health of the Earth. The monitoring of these events and the understanding of the impact which they could have on the fragile biophysical mechanisms are becoming more and more important than in the past. For this reason, sensors like Medium-Spectral Resolution Imaging Spectrometer (MERIS), Moderate Resolution Imaging Spectroradiometer (MODIS), and Advanced Very High Resolution Radiometer (AVHRR) have been designed and placed in orbit. These measurements are performed using several spectral bands (up to 36 for MODIS) located into the visible and the infrared range in order to collect a noteworthy dataset for every kind of global investigation (land use, ocean color, snow cover, sea ice observation, etc.). A following step has been the allocation of many contiguous and narrow bands (more than one hundred) available for the measurement. This technological evolution led to the hyperspectral imagery, which has demonstrated very high performance in several cases of material identification and urban mapping, including sub-pixel classification. Managing such dissimilar type of data is not a simple task and requires the adoption of information extraction techniques that are appropriate for each specific sensor data. From this point of view, a hyperspectral sensor can be considered as an extremely precise and sensitive optical sensor. However, due to its sensitivity, a hyperspectral sensor, compared to a multispectral one, is more prone to be affected by imprecise measurements. The precision of a measurement is determined by the instrument response R . The transformation from the input physical quantity I to the measurement O is described mathematically by the convolution:

The instrument response depends on several factors, such as optical imperfections, image motion, the nonzero spatial area of each detector, as well as the filtering produced by electronic elements. Except for the image motion, all the elements influencing the instrument response can be attributed to the acquisition mode. In particular the type of scanning system and the spectral selection mode can have a strong impact on the precision of the measurements.

In general, an optical sensor can be divided into three different scanning systems for acquiring the image: whiskbroom, pushbroom, and staring imagers. While whiskbroom scanners have a simple optical system and can acquire image in a wide swath width, if compared to the pushbroom scanners, their mechanical system is extremely complex expensive and prone to damages. For these reasons pushbroom scanners are considered as the standard for high-resolution imaging spectrometers. Another characteristic that can influence the hyperspectral measurement is the spectral selection mode. In particular, the spectral selection modes used in hyperspectral sensors can be divided in three main groups: dispersion elements, where the incoming electromagnetic radiation is separated into different angles by means of a prism or grating elements; filter-based elements, based on optical bandpass filters (tunable filters, discrete filters, and linear wedge filters); and Fourier-transform spectrometers (FTS): a Fourier-transform spectrometer is an adaption of the Michelson interferometer where a collimated beam from a light source is divided into two by a beam splitter and sent to two mirrors. These mirrors reflect the beams back along the same paths to the beam splitter, where they interfere. The signal recorded at the output depends on the wavelength of the light and the optical path difference between the beam splitter and each of the two mirrors. If the optical path difference between the two beams is zero or a multiple of the wavelength of the light, then the output will be bright; otherwise if the optical path difference is an odd multiple of

half the wavelength of the light, then the output will be dark.

Hyperspectral Sensors

Most of the developed hyperspectral sensors are designed for airborne carriers. One of the first airborne hyperspectral sensors was the AVIRIS (Airborne Visible/Infrared Imaging Spectrometer) developed by National Aeronautics and Space Administration (NASA). AVIRIS contains 242 different detectors, each with a bandwidth of approximately 10 nm, allowing it to cover the entire range between 380 nm and 2,500 nm. Similar sensors were the Compact Airborne Spectrographic Imager (CASI), able to acquire images in 288 bands in the 380 nm–1,050 nm spectral range, and the Hyperspectral Mapper (HyMap) providing 128 bands in the wavelength region of 450–2,500 nm. The Airborne Hyperspectral Scanner (AHS) and the Multispectral Infrared and Visible Imaging Spectrometer (MIVIS) extended the spectral range up to thermal infrared, allowing a wider range of applications.

The development of hyperspectral technology for the space satellites remains difficult and very expensive in terms of payload design, maintenance, and calibration. However, these difficulties have not deterred the space agencies from finding interesting missions carrying on board hyperspectral payloads. This is the case of Hyperion developed by NASA, CHRIS (Compact High Resolution Imaging Spectrometer) PROBA-1 (Project for On-Board Autonomy) developed by a European consortium founded by European Space Agency (ESA), the upcoming PRISMA developed by ASI (Agenzia Spaziale Italiana), and EnMAP (Environmental Mapping and Analysis Program) developed by Deutschen Zentrums für Luft- und Raumfahrt (DLR).

Hyperion instrument, mounted on board of the EO-1 (Earth Observation 1) satellite, provides a high-resolution hyperspectral imager capable of resolving 220 spectral bands (from 400 to 2,500 nm) with a 30 m spatial resolution. The instrument covers a 7.5 km by 100 km land area per image and provides detailed spectral mapping

across all 220 channels with high radiometric accuracy.

CHRIS is a high-resolution hyperspectral sensor installed on board the PROBA satellite. Distinctive feature of CHRIS is its ability to observe the same area under five different angles of view in the VIS (visible)/NIR (near infra-red) bands. Another important feature of CHRIS is the ability to be reprogrammable in terms of the number of spectral bands and spectral resolution (up to 150 spectral bands with a spectral resolution of 1.25 nm). This characteristic allows the acquisition of 62 narrow and quasi-contiguous spectral bands with the spatial resolution of 34–40 m or only 18 spectral bands with an enhanced spatial resolution of 18 m.

PRISMA (PRecursore IperSpettrale della Missione Applicativa) is a new earth observation integrating a hyperspectral sensor with a panchromatic camera. The advantage of using both sensors is to integrate the classical geometric feature recognition to the capability offered by the hyperspectral sensor to identify the chemical/physical feature present in the scene. The primary applications will be the environmental monitoring, geological and agricultural mapping, atmosphere monitoring, and homeland security.

The main goal of EnMAP project is to investigate a wide range of ecosystem parameters encompassing agriculture, forestry, soil and geological environments, coastal zones, and inland waters. Thanks to the chosen sun-synchronous orbit, each point on earth can be investigated and revisited within 4 days.

Hyperspectral Data Processing

Since hyperspectral sensors are able to measure the radiance, one of the most important processing steps in hyperspectral image processing is the conversion to reflectance. Usually, the techniques for retrieving surface reflectance can be roughly divided into two major categories, relative reflectance retrieval techniques and absolute reflectance retrieval techniques. Relative reflectance retrieval is based on the knowledge of two or more target reflectances in the image. Knowing the reflectance of

a material in the image permits to define by regression a linear equation between each wavelength and the measured radiance. However, this approach is also based on the assumption that the atmosphere is uniform, resulting in significant artifacts in strong atmospheric bands if ranges of elevations are present in the scene.

Absolute approaches, on the other hand, permit the retrieval of surface reflectance based on the physical principles, in which measured radiance is typically compared to radiance generated by an atmospheric radiative transfer model, such as the MODerate resolution atmospheric TRANsmission (MODTRAN) model. Usually, the relative approach can be useful in processing airborne data, where the influence of the atmosphere is not relevant and can be considered uniform. On the other hand, absolute approaches are dominant in spaceborne images.

Another common preprocessing step is georectification, used to relate the acquired data to the ground.

In order to make maps and relate them to ground reference data, it is critical that aircraft-related and ground-related distortions are removed. The most common approach is to use a “rubber-sheet” stretching approach and numerous tie points between a base map and measured image. Recent improvements in onboard navigation information and recent software development have made it possible to georectify images to within a few pixels (~ 10 m for a 4 m GIFOV [Ground instantaneous field of view]) in a near-automated fashion.

Aside from the common processing techniques to obtain images more interpretable, there are other techniques that are more related to the dimension of hyperspectral data. If we consider the consistency of the hyperspectral data, we can easily understand the importance of finding a method which can transform the original data cube into one with reduced dimensionality and maintain, at the same time, as much information content as possible. In particular, dataset composed of hundreds of narrowband channels, besides storage and transmission, may cause problems in terms of complexity of processing and inversion phases. Therefore,

dimensionality reduction may become a key parameter to obtain a good performance.

These techniques are known under the general name of feature reduction. Besides enabling an easier storage and management of the data, feature-reduction procedures can be crucial for the implementation of optimum inversion algorithms.

Many methods have been developed to tackle the issue of high dimensionality of hyperspectral data (Serpico and Bruzzone 1994). In summary, we may say that feature-reduction methods can be divided into two classes: “feature-selection” algorithms (which suitably select a suboptimal subset of the original set of features while discarding the remaining ones) and “feature extraction” by data transformation which projects the original data space onto a lower-dimensional feature subspace that preserves most of the information, such as nonlinear principal component analysis (NLPCA; Licciardi and Del Frate 2011).

The first analysis suggests that feature selection is a more simple and direct approach compared to feature extraction and that the resulting reduced set of features is easier to interpret. Nevertheless, extraction methods can be expected to be more effective in representing the information content in lower dimensionality domain.

Feature-selection techniques can be generally considered as a combination of both a search algorithm and a criterion function. The solution to feature-selection problem is offered by the search algorithm, which generates a subset of features and compares them on the basis of the criterion function. From a computational viewpoint, an exhaustive search for the optimal solution becomes intractable even for moderate values of features (Siedlecki and Sklansky 1988). Despite these apparent difficulties, many feature-selection approaches have been developed (Serpico and Bruzzone 1994). The sequential forward selection (SFS) and the sequential backward selection (SBS) techniques are the simplest suboptimal search strategies: they can identify the best feature subset achievable by adding (to an empty set in SFS) or removing (from the complete set from SBS) one feature at a time, until the desired number of features is achieved.

The sequential forward floating selection (SFFS) and the sequential backward floating selection (SBFS) methods improve the standard SFS and SBS techniques by dynamically changing the number of features included (SFFS) or removed (SBFS) at each step.

A feature-extraction technique aims at reducing the data dimensionality by mapping the feature space onto a new lower-dimensional space. Both supervised and unsupervised methods have been developed. Unsupervised feature-extraction methods do not require any prior knowledge or training data, even though these are not directly aimed at optimizing the accuracy in a given classification task. The class comprises the “principal component analysis” (PCA, Fukunaga 1990), where a set of uncorrelated transformed features is generated; the “independent component analysis” (ICA) (Jutten and Herault 1991), a computational method for separating a multivariate signal into additive subcomponents supposing the mutual statistical independence of the non-Gaussian source signal; and the “maximum noise fraction” (MNF, Green et al. 1988), where an operator calculates a set of transformed features according to a signal-to-noise ratio optimization criterion.

Challenges in Hyperspectral Data Processing

The analysis of hyperspectral images is not an easy task. Due to the complexity of a hyperspectral sensor, hyperspectral images can be affected by several problems in terms of data uniformity. Any nonuniformity in the system generates degrading artifacts. Since pushbroom scanners mainly characterize hyperspectral sensors, in this entry we will focus on the main problems that afflict this kind of sensors.

In pushbroom imaging spectroscopy, the image is generated in the spectral and spatial dimension simultaneously. This leads to two main kinds of problems:

- Spectral nonuniformity: is the nonuniformity of the spectral response within a sensor’s spectral band and can be imaged on a detector row. This nonuniformity is typically represented by the position and shape of the spectral response

function. The related artifacts of spectral misregistration are denoted as “smile” or “frown.”

- Spatial nonuniformity: is the nonuniformity of the spatial response within an acquired spectrum and is usually imaged on a detector column. This nonuniformity is represented by the position and shape of the spatial response function in both the along-track and across-track dimensions of a spatial pixel. The related artifacts in the across-track dimension are denoted as “keystone.”

As for the spatial nonuniformity, the influence of the “keystone” effect results in a black pixel in the image that can be easily replaced by meaning the surrounding pixels with a 3×3 moving window. On the other hand, the removal of the “smile” effect is not an easy task. The consequence of this effect is that the central wavelength of a band varies with spatial position across the width of the image in a smoothly curving pattern. Very often the peak of the smooth curve tends to be in the middle of the image and gives it a shape of “smile” or “frown.” The effect of the smile is not obvious in the individual bands. Therefore, an indicator is needed to make evident whether or not a given image suffers from smile effect. A way to check for the smile effect is to look at the band difference images around atmospheric absorption (760 nm). In fact, the region of red-near infrared transition has high information content of vegetation spectra. This region is generally called “red edge” (670–780 nm) and identifies the red-edge position (REP). The smile effect is acute due to sharp absorption at 760 nm, which is within the red-edge region, and for this reason atmospheric correction of smiled data will be incorrect.

The methodologies developed so far can only reduce the intensity of smile effect but cannot remove it entirely, because during its life a detector element can change its response; therefore, the knowledge and the correction of this phenomenon became fundamental in the analysis of hyperspectral images.

Another problem that affects pushbroom scanners is the so-called “striping” noise. The striping

effect consists in strong variations in the average value in the column for every band of the image. Theoretically the elements of the detector array are identical. Thus, the detectors in a row should be well calibrated to provide the same output along the spatial domain, if illuminated by the same source. In the real world, a residual nonuniformity of the electro-optical response generates different transfer functions. Thermal fluctuations can cause additive small variations in the alignment of the detector, producing a non-predictable noise not constant during the time. Only the systematic knowledge of the gain function permits an accurate compensation of these fluctuations. The correction of the striping can be carried out by means of filtering approaches. This type of destriping involves two filters on the original image creating two new images, a low-pass filtered image and a high-pass filtered image, and combining the results. If both a low-pass and a high-pass filter of the same size are run on an image and then added together, the result will be the original image. The goal in choosing sizes for the two filters is to create an output for each without the unwanted striping. If the filter sizes are not the same, the result will not be exactly the same as the original. When the filter outputs are added together, the striping will have been removed or subdued. If the sizes of the two filters differ too much, artifacts may be introduced into the result.

From this brief overview of the principal preprocessing techniques, it is possible to understand the amount of efforts that are necessary in order to extract useful and reliable information from hyperspectral data.

Building Vulnerability Assessment

One of the aspects of pre-seismic event management is related to the assessment of the vulnerability of buildings in urban environment. Many features that can influence the seismic performance of a building can be extrapolated from the outside and then be detected by remote sensing instruments. From this point of view, urban areas can be considered as an ensemble of

different types of surfaces characterized by a continuous spatial change. This results in small urban structures mostly dominated by artificial (man-made) materials. The identification of these materials requires an accurate analysis of the spectral characteristics of these materials. Information about the material used in the roof of the buildings permits to determinate the construction technique of the building and consequently its level of vulnerability. The identification of the roof spectral characteristics can be useful also for the derivation of the type of urban structure where the building is located. For instance, the historical development of European countries leads the urban structure type to be correlated with a certain time period and construction style. Thus the knowledge of the urban structure type may give information about the type and age of the buildings. In particular, the necessary information for the evaluation of pre-seismic events scenarios can be resumed in the detection of the building type (i.e., the material) and in the detection of the identification of the contextual information, such as the position of each building in relation to the surrounding ones. Analysis of the geological information of the soil can be useful but become extremely difficult if performed by using remote sensing techniques in urban environment, since the soil tends to be covered by man-made structures.

Material Identification

Surface materials can be detected based on their spectral characteristics. In the literature there exist several works on the extraction of information about the material of the roofs by means of multispectral images. However, these techniques permit to identify a limited number of elements, due to the low spectral resolution of multispectral imager. For instance, multispectral images are not sufficient to differentiate between roofs and other surfaces having similar spectral characteristics, such as asphalt and bitumen used to seal rooftops. In this context hyperspectral imaging can be an extremely useful instrument for an effective estimation of the vulnerability, identifying more information about the material used in the construction of the investigated buildings.

In general, several tools have been developed to match reference spectra with those measured by an imaging spectrometer. The most common approach is based on the use of standard supervised classification techniques, where known spectra are used to determine the statistical properties of each class based on spectral characteristics. Examples of supervised classification approaches applied to hyperspectral data are described in McKeown et al. (1999) and Roessner et al. (2001), where the maximum likelihood classifier (MLC) was applied to map urban land cover. Other techniques are based on the use of support vector machines (SVM) (Melgani and Bruzzone 2004) and neural networks (NNs) (Licciardi et al. 2009, 2012). Other approaches have been designed explicitly for the analysis of imaging spectrometry data, such as the Spectral Angle Mapper (SAM; Kruse et al. 1993).

In order to extract as much information content as possible from hyperspectral images in urban environment, specific methods for automated information extraction have been developed (Roessner et al. 2001). In all these methods, the comprehensive mapping of the different surfaces present on urban environment can be obtained through a classification technique (Roessner et al. 2001).

For example, Clark et al. (2001), in their environmental studies on the World Trade Center area after the September 11, 2001, attack, successfully applied hyperspectral remote sensing to map material in the surrounding area. In this study, the authors used high-spatial-resolution AVIRIS data acquired over the World Trade Center to map thermal sources, asbestiform minerals, and dust and debris from the collapse, producing maps of environmental contaminants that are difficult to produce cost-effectively in any other way. McKeown et al. (1999) used data acquired by the Hyperspectral Digital Imagery Collection Experiment (HYDICE) to classify urban and natural materials. The authors then fused the classification results with a 3D model of the buildings. Ben-Dor (2001) developed an urban spectral library using a combination of an existing spectral library developed by Price (1995) and CASI data acquired over the city of

Tel Aviv, Israel. Data acquired by the Digital Airborne Imaging Spectrometer (DAIS) have been used by Roessner et al. (2001) to obtain a map of urban materials in the city of Dresden, Germany. In this study, a maximum likelihood classifier has been used to derive a first map of pure spectral features and then used these features to unmix the other spectra.

However, since the spectral variations characterizing a certain material are caused by several factors, such as the age and deterioration of the material, or the color, and also by the illumination angles, several aspects need to be considered. In particular, aside from the spectral heterogeneity of different materials, it is important to take into account the high intra-class variability of spectra corresponding to the same material. Moreover, in urban environment there are many objects having a size smaller than the pixel. This results in mixed pixels, presenting spectra that are a combination of two or more materials that are imaged in the IFOV (instantaneous field of view) of the sensor. Moreover, the modeling of the spectral mixture becomes more complex as the pixel size increases. From this point of view, airborne hyperspectral sensors, characterized by a high spectral and/or spatial resolution, permit to obtain reliable quantitative measurements of specific absorption features of urban materials.

In terms of spectral unmixing, a number of approaches in the literature are based on the assumption that the detected spectra are linear combination of pure spectra. In particular, in linear spectral unmixing the mixed spectrum is modeled as the sum of pure spectra, each weighted by the fraction of the material within the field of view. Roberts et al. (1998) have developed a general approach for spectral unmixing in which the number and types of end-members are allowed to vary per pixel. In Roessner et al. (2001), the authors used an MLC to detect the pure spectra in the image and then use them as end-members to produce the abundance maps. An approach based on nonlinear unmixing has been proposed in Licciardi and Del Frate (2011), where a neural network (NN) has been used to quantify the abundances of previously detected end-members.

Fusion of Hyperspectral and Geometric Information

While the spectral information is extremely useful to identify different materials, it does not provide any information on the use of these materials. This means that spectral information is not sufficient to differentiate, for instance, a roof from other surfaces characterized by the same material. For this reason, additional information is required for the univocal identification of the buildings. One possible solution is to derive the shape characteristics of the buildings present in the image. Usually, when seen from above, most of the buildings present a rectangular shape. However, some exceptions exist in terms of regularity of the shape. For instance, industrial or commercial buildings present differences in terms of size and covering materials, such as bitumen or metal. Residential buildings are, on the other hand, of small size and often covered with tiles or concrete. Roads are characterized by bitumen but present oblong shapes and sometimes interrupted by the tree canopies. Parking lots are spectrally characterized by bitumen but, differently from the roads, are characterized by rectangular shapes. This requires the development of algorithms, which can handle this variety in the shape detection process. The basic approach for the extraction of objects is segmentation, consisting in labeling each pixel in the image and grouping the adjacent ones according to their label. In the literature a variety of methods for segmentation of hyperspectral image exist. Segl and Kaufmann (2001) proposed a method for the identification of buildings based on an iterative segmentation followed by a classification. In Tarabalka et al. (2010), the watershed segmentation algorithm has been applied to hyperspectral images, while in Priego et al. (2013), a segmentation technique based on the application of cellular automata is used in order to produce homogeneous regions. In both cases an support vector machine (SVM) approach is applied to label the obtained objects and classify them. The use of geodesic opening and closing operations of different sizes in order to build a morphological profile and a neural network approach for the classification of features has

been introduced in Pesaresi and Benediktsson (2001) and applied successfully to hyperspectral data in Licciardi et al. (2012).

An emerging technique in the last decades is based on the fusion of hyperspectral and Light Detection and Ranging (LiDAR) data, thanks to the increased availability of these data taken from the same area. In particular, in urban environment, the introduction of high-resolution digital surface models derived from LiDAR can effectively improve the classification and consequently the identification of different materials and surfaces.

In Heiden et al. (2012), the height information obtained from LiDAR data has been introduced into orthorectification in order to improve the geometric accuracy of urban objects in the higher-resolution hyperspectral image data. This permitted to eliminate the influence of the facades of the buildings in large field of view (FOV) of such sensors and to improve the accuracy of surface material mapping.

The fusion of LiDAR and hyperspectral data through a physical model has been used in Zhang et al. (2013) to eliminate the direct illumination component in the hyperspectral radiance data and consequently permitted to detect also materials under shadows.

Change Detection

The accurate analysis of the spectral characteristics of the materials present in urban environment covers an important role in the framework of building vulnerability assessment. However, a complete analysis of the vulnerability of buildings in urban environment and more in general environmental monitoring requires also an accurate study of the changes occurred in the time domain. From this point of view, the monitoring of urban areas using multi-temporal images has received increasingly attention in the last decades. In particular, remote sensing technology is able to provide a large amount of images on the same area over a long period of time. Land-cover change detection is a useful instrument for the description of changes in urban environments. Change detection by remote sensing has been widely used in many applications such as

land-use/land-cover monitoring, urban development, and ecosystem and disaster monitoring. Conventional change detection methods generally depend on a difference value in each individual band, such as image differencing or the image ratio. However, most of these methods are based on multispectral images and do not take into account the physical meaning of the continuous spectral signatures. In hyperspectral images, the change can be associated to change of a spectral signature from one material to another material. For this reason most of the techniques presented in the literature are based on the difference in the spectral signatures of different materials. However, the detection of changes in hyperspectral images is not a trivial task, mainly because of several factors influencing the final result. Problems that can complicate the detection of changes in urban environment are caused by differences in the illumination level, such as the presence of shadows in two different images. Geometrical differences in terms of parallax and error of misregistration may result in the detection of false changes, as well as differences in atmospheric content. Moreover, since different cities may present different patterns and characteristics, it is difficult to define a general technique that can be applied indifferently to any kind of urban pattern. In the literature the existing change detection techniques can be divided into three main groups.

Post-classification methods are easy to implement and provide “from-to” change maps but may present limits in their validity because of misclassification errors in one of the classification maps. Other methods are based on image transformation techniques such as PCA or multivariate alteration detection (MAD). These techniques project the original hyperspectral data into a feature space in order to label the changes (Nielsen et al. 1998). A third kind of hyperspectral change detection methods is based on the detection of anomalies present in the images. In particular, anomaly detection techniques are able to distinguishing unusual targets from a typical background, and this assumption can be extended to change monitoring (Eismann et al. 2008).

Summary

In this entry we provided a brief description of the different aspects of the use of hyperspectral data in urban environment. In the introduction we presented a brief overview of imaging spectrometry in urban areas. The discussion continued with a description of the characteristics of the hyperspectral sensors and the problems related to the processing of hyperspectral images. We illustrated then the different techniques for the assessment of building vulnerability through the use of hyperspectral data.

The management of pre-seismic event in urban environment can be improved with the use of remote sensing data. In recent years remote sensing becomes more and more a popular instrument in the monitoring of urban areas since many features influencing the seismic performance of a building can be extrapolated from remote sensing instruments. Hyperspectral sensors, able to provide images with unprecedented spectral detail, can have an important role in the assessment of the vulnerability of buildings in urban environment. From this point of view, urban environment is extremely challenging because of the need to discriminate as much materials as possible. Hyperspectral sensors, able to provide images with unprecedented spectral detail, can have an important role in the assessment of the vulnerability of buildings in urban environment. However, this task is often complicated by several factors, such as the different reflectance of the material, different lighting conditions, as well as different atmospheric characteristics. To solve these problems, several techniques have been developed in order to obtain efficient mapping of urban materials with the use of hyperspectral images.

Incremental Dynamic Analysis

Dimitrios Vamvatsikos

School of Civil Engineering, National Technical
University of Athens (N.T.U.A.), Athens, Greece

Introduction

An important issue in performance-based earthquake engineering is the estimation of structural performance under seismic loads. In particular, one is interested in estimating the probabilistic distribution of structural response in the form of engineering demand parameters (EDPs) such as peak interstory drift, peak floor acceleration, moment, or shear, given the level of seismic intensity represented by a (typically scalar) intensity measure (IM). Incremental dynamic analysis (IDA) has been developed to provide such information by employing nonlinear dynamic analyses of the structural model under a suite of ground motion records, each scaled to several intensity levels designed to force the structure all the way from elasticity to final global dynamic instability.

The use of ground motion scaling for determining the response of a structure at increasing levels of intensity is an old technique. Still, it had not been used systematically to quantify the probabilistic nature of structural response until the start of the SAC/FEMA (2000a, b) project that was conceived in the aftermath of the Northridge

1994 earthquake. Therein, a precursor to IDA was proposed in the form of the “dynamic push-over,” a method to determine the global collapse capacity of structures (Luco and Cornell 1998). Subsequently, this was recast and formalized by Vamvatsikos and Cornell (2002) as a comprehensive procedure to assess the statistics of EDP demand given the IM as well as the required (“capacity”) IM to achieve given values of EDP at any level of structural behavior. It is this format that is known as IDA and will be described in the following sections, discussing the necessary steps and concepts in executing, postprocessing, and applying IDA to solve problems of engineering significance.

Intensity Measure and Ground Motions

First and foremost for IDA, an efficient and sufficient IM (Luco and Cornell 2007) should be selected. An efficient IM will generally be well correlated with the EDPs of choice, thus showing low dispersion of demand given the IM and subsequently allowing the determination of EDP demand or IM capacity statistics using a relatively low number of ground motion records. In other words, efficiency is synonymous with economy in computational resources, becoming a nontrivial issue when considering that a single nonlinear dynamic analysis of a moderate complexity model can easily last more than 30 min. The second requirement, sufficiency, is defined

as the independence of the distribution of EDP given the IM from any other seismological parameters that may characterize the ground motion, e.g., duration, magnitude, spectral shape, or the presence of a pulse indicative of near-source forward directivity. A sufficient IM essentially captures all seismological information needed to determine the effect of a ground motion record on the structure being investigated, thus allowing unrestricted scaling in theory. Naturally, any IM for which a seismic hazard curve can be practically estimated will never be fully sufficient; thus, excessive scaling may introduce biased estimates of response (Luco and Bazzurro 2007).

A standard choice used in the literature is the 5 % damped first-mode (pseudo)spectral acceleration $S_a(T_1)$ (Shome et al 1998; Shome and Cornell 1999). This is generally adequate for first-mode-dominated structures that do not displace far into the nonlinear region, as is the case of most existing brittle or moderately ductile low/mid-rise buildings. For taller or asymmetric structures where higher modes become important or modern buildings that exhibit significant ductility, improved IM alternatives should be sought. One particularly attractive option is the geometric mean of spectral acceleration values at several periods (Cordova et al 2000; Vamvatsikos and Cornell 2005; Bianchini et al 2009) or an inelastic spectral displacement-based IM (Luco and Cornell 2007). Both can largely alleviate the effect of spectral shape, being able to capture the period elongation characterizing ductile structures and the effect of higher modes.

In terms of selecting ground motion records, the general idea is to reduce the bias that a less than ideal IM may introduce. A general rule of thumb is to utilize accelerograms that can significantly damage the investigated structure without much scaling. For modern ductile structures, this generally means records having naturally high $S_a(T_1)$ values. Still, IDA is structured in such a way that the same set of records is used throughout the entire range of structural behavior (elastic–inelastic collapse). Whenever site conditions are deemed to have different impact at

different levels of intensity, thus fundamentally changing the nature of records that one would use at low versus high levels of the IM, then methods of analysis other than IDA should probably be employed.

Structural Model

For performing IDA, a (a) realistic, (b) low-to-medium-complexity, (c) robust nonlinear structural model should be formed. Each of these three requirements comes with its own reasons.

For one, realism means incorporating all pertinent sources of material and geometric nonlinearity that are expected to arise. This should include, for example, plastic-hinge formation zones for moment-resisting frames, brace buckling for braced frames, and P-Delta effects. Nonsimulated failure modes, such as the shear failure of members or the brittle failure of beam–column joints, can be incorporated in the analysis a posteriori. Still, they essentially remove the model's ability to track structural behavior beyond their first occurrence. This means that whenever nonsimulated failures are found to have occurred, one cannot trust the model to provide estimates beyond that point.

The requirement of low-to-moderate complexity is necessary for ensuring that the computationally intensive IDA will generally be confined to reasonable amounts of time. Complex nonlinear models can complicate the execution to no end, easily forcing each nonlinear analysis to last several hours or, worse, often forcing the analyst to consider reducing the number of records or dynamic runs per record employed. This can be a tricky situation that may lead to inaccurate or biased results. Thus, it is best to strike a trade-off between model complexity and fidelity, striving to find a good balance that allows using a rich set of at least 20–30 ground motion records with six or more time history analyses for each.

Finally, robustness becomes important in tracking structural behavior in the postelastic region, especially beyond the structure's

maximum-strength point, where it starts deteriorating and approaching collapse. To be able to ensure such results, a highly reliable software platform should be used. IDA by nature will drive both the model and the analysis software to their limits, making robustness difficult to achieve. Even then, typical complex finite element models that have been used successfully for elastic or mildly inelastic analysis tend to fare poorly when driven close to global dynamic instability, being consistently less reliable than their simpler versions besides significantly raising the computational cost. For example, it is often the case that distributed plasticity models are numerically less stable and always more expensive than lumped-plasticity ones. Therefore, considerable attention should be paid to the formation and testing of the model before IDA is performed, checking its behavior and stability via nonlinear static pushover analyses.

Execution

Performing IDA is conceptually simple. One only needs to take one record at a time, incrementally scale it at constant or variable IM steps, and perform a nonlinear dynamic analysis each time. Start from a low IM value where the structure behaves elastically, and stop when global collapse is encountered. The latter is defined as the occurrence of a nonsimulated failure mode or the appearance of a global dynamic instability as a collapse mechanism showing “infinite” EDP values at a given IM level. For a well-executed analysis and robust structural model, global dynamic instability manifests itself as numerical nonconvergence.

Selecting constant IM steps is often the simplest but also the most wasteful approach to IDA. As global collapse is encountered at widely varying IM levels for each record, some ground motions will require twice or thrice the dynamic analyses than others. Using variable IM steps estimated via the hunt & fill procedure of Vamvatsikos and Cornell (2002, 2004), offers instead consistent accuracy at a predefined

computational cost. Due to the nearly perfect computational independence of each dynamic analysis, IDA execution is an easily parallelizable problem (Vamvatsikos 2011). Hence, one can benefit from using a cluster of N computers to divide the total running time (almost) by N . Such savings make possible the use of Monte Carlo-based algorithms (Vamvatsikos 2014) to economically estimate any bias and additional variability introduced by modeling uncertainty.

Postprocessing

The results of IDA initially appear as distinct points, one per each dynamic analysis, in the EDP versus IM plane, as observed in Fig. 1 for a nine-story steel moment-resisting frame. Linear or spline interpolation (Vamvatsikos and Cornell 2004) is then employed to generate continuous IDA curves, one for each individual ground motion record, shown in Fig. 2. The variability offered by such curves is actually one of the eye-opening features of IDA, visually representing the probabilistic nature of seismic loading and the differences introduced even by (seemingly) similar ground motions. At the highest IM level that each IDA curve can reach, one can identify the characteristic flatline representing global collapse. In the example of Fig. 2, this is the intensity where the maximum (over all stories) peak interstory drift (the EDP of choice) increases without bound for each record, leading to global system collapse.

The complex picture of structural response shown by the IDA curves can be significantly simplified by summarizing them into the 16/50/84 % fractile curves shown in Fig. 3. This is simply the determination of the 16/50/84 % percentile values of EDP at each level of the IM, taking horizontal cross sections of the IDA curves or, equivalently, the 84/50/16 % percentiles of the IM given the EDP when vertical cross sections are assumed instead. The three curves of Fig. 3 thus provide the full characterization of the distribution of structural response via the central

Incremental Dynamic Analysis, Fig. 1 The resulting IM-EDP points for 30 ground motion records when performing IDA for a 9-story steel frame using $S_a(T_1)$ as the IM and the maximum over all stories peak interstory drift $\theta_{\max}$ as the EDP

Incremental Dynamic Analysis, Fig. 2 The 30 IDA curves derived by interpolating the IM-EDP points of Fig. 1 for the 9-story steel frame

value (median) and the dispersion of EDP structural demand given the IM. For the example of the nine-story steel frame, one can observe how the median demand obeys the “equal displacement” rule, originally suggested by Veletsos and Newmark (1960) for elastoplastic single-degree-of-freedom systems: The median IDA maintains the same slope in the elastic and the inelastic range, meaning that an elastic version of this nine-story steel frame subject to the same level of ground motion would (in the median sense)

experience the same maximum interstory drift as the inelastic one. This only changes when the structure enters into the “negative stiffness” range where its strength starts degrading and the 50 % IDA deviates to the right to merge into the flatline representing the median IM collapse capacity value.

Finally, one can employ the IDA curves to define appropriate limit states and estimate the corresponding IM values of capacity. A limit state is usually tied to specific threshold EDP

Incremental Dynamic

Analysis, Fig. 3 The 16/50/84 % fractile IDA curves obtained by summarizing the individual IDA curves of Fig. 2 for the 9-story steel frame

Incremental Dynamic

Analysis, Fig. 4 Thirty IDA curves, 30 limit-state capacity points and the corresponding EDP and IM capacity distributions for the 9-story steel frame (From Vamvatsikos 2013)

capacity values of one or more EDPs that can be either deterministic, i.e., assumed to be perfectly known, or probabilistic, the latter obviously being the more realistic option. When such threshold values are exceeded, the limit state is deemed to have been violated. The first (in terms of the lowest IM) exceedance of the limit state appears as a single point on each IDA curve (Fig. 4). The resulting distribution of IM coordinates (or IM capacities) of the limit-state points

can be used to define the so-called fragility functions, as discussed in the following section.

Use and Applications

IDA has found numerous uses within the framework performance-based earthquake engineering. The three main applications are discussed below.

First, IDA curves can be employed to evaluate fragility curves. A building-level fragility curve is a probability-valued function of the IM. It represents the probability of violating a limit state given the IM level. In terms of IDA, all that is needed is the determination of the limit-state points for each IDA curve. In the case where a single EDP is used to test for limit-state violation, these can be simply defined by simulating equiprobable values of the (random) EDP capacity. Then, one only needs to find the lowest-IM point on a given IDA curve that corresponds to each given EDP value of capacity. For example, when the EDP capacity is deterministic, all such points will align themselves along a single vertical line in the IM-EDP plane that intersects the horizontal axis at that specific value of EDP capacity. In either case, the cumulative distribution function (CDF) of the IM coordinates (or IM capacities) of the limit-state points (Fig. 4) directly provides the corresponding fragility curve. One can either employ the empirical CDF or an analytical approximation (typically via a lognormal assumption) to obtain either a point-by-point accurate estimate of the fragility curve or instead offer a simple (two-parameter) fit.

Second, the results of IDA either in their summarized form (Fig. 3) or as raw IDA curves (Fig. 2) are used within PEER-style frameworks (Cornell and Krawinkler 2000) to determine the distribution of EDP demand given the IM or P (EDP|IM) for any story or component of interest. As such, it is often one of the prominent methods employed for building seismic loss assessment, most notably in FEMA P-58 (FEMA 2012). The results of IDA are essentially convolved with the seismic hazard and appropriate loss/downtime/casualty calculations to derive the mean annual frequency of exceeding any specified level of repair cost, time to repair, or number of people injured or dead.

Finally, IDA has been adopted as the method of choice for determining strength reduction R-factors for USA, as presented in FEMA P-695 (FEMA 2009). R-factors, also known as behavior q-factors, are used in every modern seismic code to appropriately reduce the required design strength of a structure to take advantage of its

ductility. Their assessment requires a careful evaluation of the collapse capacity of a comprehensive set of archetypes to ensure that a structure designed according to the specified reduced strength can still offer the required level of safety.

Summary

Incremental dynamic analysis is a method for assessing the distribution of structural response at every level of structural behavior from elasticity to final global dynamic instability. It employs numerous nonlinear dynamic analyses of the structural model subject to a suite of ground motion records that are scaled to multiple levels of intensity. By interpolating such results and appropriately summarizing them, one can estimate any desired statistic of response given the seismic intensity. Additionally, using the IDA results, any number of limit states from minor damage to global collapse may be defined, and the associated fragility functions can be effortlessly estimated. Still, to preserve the validity of such results and ensure unbiased estimation, attention should be paid to the ground motions used and the intensity measure selected to represent them. Then, IDA becomes a powerful tool for performance-based assessment of structures, factually linking seismic hazard and structural behavior to estimate losses, downtime, and casualties.

Introduction

The SAR technique allows the formation of high-resolution radar images from the data acquired by side-looking instruments installed on spacecraft, aircraft, or the ground. The fundamentals underlying SAR image processing are presented in Chapter 3 “► [SAR Images, Interpretation of](#)”. Each pixel of an image corresponds to the

InSAR and A-InSAR: Theory, Fig. 1 Images formed from Envisat data acquired 35 days apart over north Iceland: (a) amplitude of master acquisition, (b) raw interferogram, (c) simulated reference phase projected onto interferometric amplitude, and (d) interferogram after reference phase is subtracted from the raw interferogram

phase. The perpendicular baseline between the two acquisition geometries is 63 m, giving an altitude of ambiguity of 145 m. In other words each fringe in (d) represents another 145 m of elevation, meaning that the a large volcano just east of center (Kollóttadyngja) rises $\sim 3 \times 145 = 435$ m above the surroundings

scattered signal from a resolution element on the ground, which is transmitted and received by the SAR. A pixel is characterized by two values: the amplitude and the phase. While the amplitude of

a single image can be interpreted in terms of the backscattering properties of the ground (Fig. 1a), the phase is not very informative because it is a pseudorandom contribution from the

configuration of all scatterers within the resolution element. However, provided that the scattering properties of the element are similar for the two acquisitions, the difference in phase between two images can be interpreted in terms of the change in range between the radar instrument and the target, which is the principle of SAR interferometry (InSAR).

For two SAR images acquired at the same moment from slightly different positions, the change in range can be interpreted in terms of the topography, allowing for the production of digital elevation models. For two images acquired at different times, movement of the ground between acquisitions can also contribute to the change in range. Thus, InSAR is also a powerful technique for measuring deformation of the ground, and this is the most common application of InSAR (sometimes referred to as differential InSAR or DInSAR). While the InSAR technique is applied to individual pairs of images, advanced InSAR (A-InSAR) techniques have been developed to analyze multiple SAR images together. These have the advantage of allowing

error terms to be better estimated and also provide a framework for looking at the temporal evolution of deformation.

Since the launch of ERS-1 by the European Space Agency (ESA) in 1991, there has always been at least one SAR satellite in operation. Therefore, in addition to the ability to use InSAR to monitor ongoing deformation, there is a long archive of data that allows us to also look at deformation that occurred in the past. In the past two decades, SAR satellites have evolved from mostly C-band sensors with ground-pixel resolutions of tens of meters to C-, X-, and L-band systems that can have spatial resolutions better than 1 m, with some satellites flying in formation or as part of a constellation. Currently, we are entering a golden age for InSAR, with a new generation of satellite missions that have been launched recently or will be launched in the next few years. These include ESA's Sentinel-1 – the first SAR mission that is operational in nature rather than purely scientific, with data being available within minutes of acquisition. A list of all satellites useful for InSAR is provided in Table 1.

InSAR and A-InSAR: Theory, Table 1 Past and present side-looking SAR satellite missions (as of 1 November 2014)

Mission	Period of operation	Wavelength (cm)	Orbit repeat (days)
SEASAT	Jun–Oct 1978	23.5	17
ERS-1	Jul 1991 to Mar 2000	5.66	3 or 35
ERS-2	Apr 1995 to Sep 2011	5.66	3 or 35
JERS-1	Feb 1992 to Oct 1998	23.5	44
SIR-C/X-SAR	9–20 Apr 1994 and 30 Sep to 11 Oct 1994	23.5, 5.8 and 3	N/A
RADARSAT-1	Nov 1995 to present	5.6	24
SRTM	11–22 Feb 2000	5.8 and 3.1	N/A
Envisat	Mar 2002 to Apr 2012	5.63	35 ^a
ALOS	Jan 2006 to Apr 2011	23.5	46
COSMO-SkyMed (constellation of four satellites)	Jun 2007 to present	3.1	16
	Dec 2007 to present	3.1	16
	Oct 2008 to present	3.1	16
	Nov 2010 to present	3.1	16
TerraSAR-X	Jun 2007 to present	3.1	11
TanDEM-X	Jun 2010 to present	3.1	11
RADARSAT-2	Dec 2007 to present	5.6	24
Sentinel-1	2014 to present	5.6	12 ^b
ALOS-2	2014 to present	23.5	14

^aFrom November 2010 to the end of its operation, Envisat operated in a 30 day orbit, which was not optimal for interferometry at high latitudes

^bIn 2016 a second Sentinel-1 satellite will be launched reducing the repeat time to 6 days

In this entry, the theory behind InSAR is described, including all the necessary steps to form and interpret an “interferogram.” Subsequently the major A-InSAR algorithms are described.

InSAR

Two SAR images acquired from approximately the same look direction can be combined to form an interferogram. The phase of an interferogram is related to the change in range between the sensor and the ground and forms the basis for interpretation in terms of ground elevation or ground deformation. This section covers the theory behind forming and interpreting a single interferogram (refer to Massonnet and Souyris (2008) for further details on processing).

Coregistration of SAR Images and Resampling

Before an interferogram can be formed from two images, the geometry of one of the images (denoted the “slave”) needs to be resampled into the geometry of the other (denoted the “master”). The reason for the difference in geometry is that the sensor acquires the images from slightly different locations. The primary difference is a translation and a linear stretch in range, although the presence of topography introduces higher-order offsets.

To carry out the resampling, the offset for each pixel must first be estimated, in a process known as “coregistration.” Coregistration can be achieved using the data themselves by cross-correlation of image amplitude, with satellite orbits being used only to estimate an initial approximate offset for the whole slave image. Range and azimuth offsets are estimated for hundreds to thousands of small subsets of the image. A 2-D polynomial is then fit to both the range and azimuth offsets, using weighting based on correlation. The polynomial, which is typically second or third order, is then used to calculate the offset for each individual pixel.

However, if the satellite orbits and the topography are accurately known, which tends to be the

case with modern satellites, it is possible to calculate the coregistration offset for each individual pixel geometrically. Amplitude cross-correlation is then used only to estimate a single offset in azimuth, due to timing errors, and a single offset in range, due to the average difference in atmospheric delay (see section “[Atmospheric Phase](#)”).

After coregistration, the slave is resampled into the master geometry by interpolation using an appropriate kernel, typically a sinc or raised cosine function, depending on the filtering that has been applied to the image. The output from the coregistration procedure is used to calculate the position of each master pixel within the slave image and the interpolation is used to calculate the value of the slave image at that point.

Raw Interferogram Formation

An interferogram is generated simply by multiplying the master image, pixel by pixel, by the complex conjugate of the resampled slave image. The phase of the interferogram is the phase difference between master and slave images and the amplitude is the product of the amplitude of the two images (Fig. 1b).

The phase of the raw interferogram contains contributions from several sources:

$$\phi = \phi_{\text{ref}} + \phi_{\text{topo}} + \phi_{\text{def}} + \phi_{\text{atmos}} + \phi_{\text{noise}}, \quad (1)$$

where ϕ_{ref} is the reference surface phase due to a difference in look angle of the master and slave (section “[Reference Phase](#)”), ϕ_{topo} is phase due to topography (section “[Topographic Phase](#)”), ϕ_{def} is phase due to deformation (section “[Deformation Phase](#)”), ϕ_{atmos} is phase due to propagation through the atmosphere (section “[Atmospheric Phase](#)”), and ϕ_{noise} is phase noise due to decorrelation and other effects (section “[Decorrelation](#)”).

Once an interferogram is generated, the next steps involve reducing the contributions from sources which are not of interest, in order to isolate those which are.

InSAR and A-InSAR: Theory, Fig. 2 Imaging geometry (not to scale; B is typically 10^3 – 10^4 times smaller than r). Master and slave sensors are flying into the page and looking down and to the right

Reference Phase

There is a contribution to the interferometric phase from the change in range resulting from the two images being acquired from different points in space. This can be separated into the reference phase expected if the ground surface were at a reference surface (e.g., WGS84) and phase due to modulation of the reference surface by topography. The reference phase can always be estimated and subtracted, although the accuracy of the estimate depends on the accuracy of the orbit data.

The change in range due to geometry for a reference surface can be estimated as follows (Fig. 2). From the law of cosines,

$$\frac{r^2 + B^2 + (r + \delta r)^2}{2rB} = \cos(\alpha + \pi/2 - \theta). \quad (2)$$

where r is the range from the satellite to the ground for the master acquisition, B (baseline) is the distance between the master and slave sensor, α is the angle between the horizontal and the baseline vector, and θ is the look angle. Neglecting second-order terms in δr^2 and B/r , this reduces to

$$\delta r = -B \left(\sqrt{1 - \frac{z_0^2}{r^2}} \cos \alpha - \frac{z_0}{r} \sin \alpha \right), \quad (3)$$

where z_0 is the height of the sensor above the reference surface. Change in range is converted into interferometric phase by dividing by the wavelength, λ , multiplying by -4π (-4π rather than -2π as the signal travels a distance $2\delta r$ farther), and dropping whole phase cycles. The reference phase, also known as “flat-Earth phase,” is then given by

$$\phi_{\text{ref}} = W \left\{ \frac{4\pi B}{\lambda r} \left(\sqrt{r^2 - z_0^2} \cos \alpha - z_0 \sin \alpha \right) \right\}, \quad (4)$$

where $W\{\cdot\}$ is the “wrapping” operator that drops whole phase cycles (Fig. 1c).

Topographic Phase

When generation of a DEM is the goal of the InSAR processing, the remaining phase is interpreted as the topographic contribution. To minimize noise from non-topographic contributions, simultaneous acquisitions therefore provide the best data for this application. In the case where isolation of another signal (usually deformation) is the goal of the processing, a DEM is used to simulate the topographic contribution and subtract it. If topography is considered as a perturbation to the reference surface, the relationship between elevation and phase can be determined by substituting z for z_0 in Eq. 4 and differentiating, giving

$$\frac{d\phi}{dz} = -W \left\{ \frac{4\pi B_{\perp}}{\lambda r \sin \theta} \right\}, \quad (5)$$

where $B_{\perp}$ is the perpendicular component of the baseline, or “perpendicular baseline.”

$\frac{d\phi}{dz}$ gives change in elevation with respect to the vertical vector below the satellite. To put topography in terms of the local vertical vector, the reference frame needs to be rotated, which has the effect that $\sin \theta$ becomes $\sin \theta_i$ where θ_i is the angle of incidence at the reference surface, rather than the look angle.

Considering only the first term in a Taylor expansion, the total geometric phase is given by

$$\phi \approx W \left\{ \phi_{\text{ref}} + \frac{4\pi B_{\perp}}{\lambda r \sin \theta_i} h \right\}, \quad (6)$$

where $h = -(z - z_0)$, the elevation above the reference surface. Topographic phase is then approximately proportional to elevation, which means that phase contours follow elevation contours, with one color “fringe” representing $\sim \lambda r \sin \theta_i / 2B_{\perp}$ m (Fig. 1d). This value is known as the *altitude of ambiguity*. Increasing perpendicular baseline therefore provides greater sensitivity to elevation and also leads to greater decorrelation (section “Decorrelation”).

Note that for greater accuracy, higher-order terms in the Taylor series must also be taken into account. Considering only the first-order term equates to a 40 m DEM error over 2,000 m of elevation change for ERS or typical Envisat acquisitions.

Given a DEM it is therefore relatively straightforward to project it into the radar coordinate system, calculate the topographic contribution to the phase using the formula above, and subtract it from the interferometric phase. Note that any errors in the DEM will lead to residual phase error that is proportional to the perpendicular baseline. Therefore, when the goal of the processing is to isolate a signal other than that due to topography, a small value for the perpendicular baseline is good for two separate reasons: firstly, the residual phase due to any DEM error is small and secondly, the geometric decorrelation is small (section “Decorrelation”).

When the aim is to generate a DEM from the interferometric phase, on the other hand, reversing the operation is not quite so simple, as the wrapping operator must first be inverted in a process known as *phase unwrapping*. This topic is covered in section “Phase Unwrapping.” Phase unwrapping provides the total phase difference (including whole phase cycles) between any two pixels, but not the absolute total phase for each pixel, so extra information is required to “tie” the DEM to the ground surface.

Deformation Phase

The most common application of InSAR is to measure deformation of the ground surface.

When an interferogram is formed between images acquired at different times, any change in range due to movement of the ground between the acquisitions will contribute to the interferometric phase; each displacement of half the wavelength of the carrier signal away from the satellite will increase the phase delay by one more phase cycle (Fig. 3):

$$\phi_{\text{def}} = -W \left\{ \frac{4\pi}{\lambda} \delta r \right\}, \quad (7)$$

where δr is the change in range. Note that only the component of any displacement in the line-of-sight direction will result in a range change, and any displacement perpendicular to the line of sight will be invisible in the interferogram.

As in the case of DEM generation (section “Topographic Phase”), to interpret the phase as displacement, it must first be unwrapped (section “Phase Unwrapping”). The resulting unwrapped phase can then be used to derive relative line-of-sight displacements between any two points in the interferogram. To derive absolute displacements, the displacement at one or more points in the interferogram must be known a priori.

Atmospheric Phase

Propagation of the signal through the atmosphere influences the phase delay, by an amount that depends on atmospheric conditions, which are spatially variable (Hanssen 2001). Most of the spatial variability in the induced interferometric phase occurs in the ionosphere and the troposphere. The influence of the ionosphere on phase delay tends to be long wavelength (hundreds of km) and, except in the case of L-band data, is commonly ignored. There are, however, several methods for estimating the effect, if necessary (Meyer 2011). Phase delay during propagation through the troposphere, on the other hand, is equally significant at all microwave frequencies and variability is significant over short distances.

Propagation through the troposphere induces an additional phase delay which depends primarily on pressure, temperature, and humidity. These properties vary on two characteristic lateral

InSAR and A-InSAR: Theory, Fig. 3 An example interferogram displaying coseismic deformation for the $M_w = 9.0$ Tohoku-Oki earthquake, Japan, which occurred on 11 March 2011. The SAR data were acquired by the L-band ALOS satellite on 28 October 2010 and 15 March 2011. In (a) the interferometric phase is displayed with each color cycle representing 11.8 cm of displacement away from the satellite, which was moving in the direction of the *white arrow* and looking in the direction of the *black*

arrow. In (b) the phase is integrated and converted to line-of-sight displacement, indicating that the southernmost point moved more than 2.5 m away from the satellite, relative to the northern end. The orbit data provided for 15 March were preliminary and so some orbital signal remains. Signal is partially lost in the mountainous regions due to decorrelation, caused chiefly by snow (Modified after Hooper et al. (2012))

length scales: a short scale (a few km) induced by turbulent troposphere dynamics and a long scale (10s of km). The long-scale variation induces not only long-wavelength artifacts but also interferometric fringes that are strongly correlated with topography, as phase delay depends on how far through the troposphere the signal has traveled.

The turbulent variation is difficult to model and currently can only be reduced by filtering in time

and space (see section “[Phase Unwrapping](#)”). However, temporal filtering methods are less successful for reducing topographically correlated delay, especially when deformation is not linear in time, because SAR data sets typically do not sample seasonal atmospheric fluctuations evenly, resulting in biased estimates.

Alternatively, topographically correlated tropospheric artifacts can be partially corrected

using the information contained within the SAR data, based on the correlation between phase and elevation in nondeforming areas. In addition, the long-wavelength artifacts can be estimated over a whole image by consideration of how this correlation varies (Bekaert et al. 2015).

Complementary data sets, such as dense GNSS or meteorological measurements acquired at the same time as the SAR images, or global meteorological models, provide an alternative method for estimating the topographically correlated and long-wavelength tropospheric artifacts (Jolivet et al. 2011).

Decorrelation

A resolution element on the ground usually contains many scatterers, all of which contribute to the echo for that element. If the scatterers move with respect to each other, the echoes from the scatterers sum differently, a phenomenon known as *temporal decorrelation*. This induces a change to the interferometric phase. The echoes also sum differently if viewed from a different angle (*geometric* or *spatial decorrelation*) or probed with a different range of Doppler frequencies (*rotational decorrelation*). There is also *thermal decorrelation* term due to the signal-to-noise properties of the radar.

How closely the phase in one acquisition tracks that of another can be measured in terms of the complex correlation coefficient, or coherence, defined as

$$\gamma = \frac{E[u_1 u_2^*]}{\sqrt{E[|u_1|^2] E[|u_2|^2]}}, \quad (8)$$

where u_1 and u_2 are the complex signals from each image and $E[\cdot]$ represents the expected value. In practice, the expected values are usually estimated as the mean values for pixels in a small spatial window. Values of $|\gamma|$ range between 0 (no correlation) and 1 (perfect correlation).

Because the contribution from decorrelation to the interferometric phase is pseudorandom, the effects can be reduced, at the cost of resolution, by averaging the signal of all pixels within a

window of some specified size, or *multilooking*, or by spatial filtering (Goldstein and Werner 1998).

Rotational decorrelation can be lessened by only using the Doppler frequencies that were used to sample both images; frequencies outside of the overlapping frequency band are discarded for each image by bandwidth filtering. This has the effect of coarsening resolution, as resolution = $1/\text{bandwidth}$. In the case of there being no overlapping bandwidth, the result is total decorrelation.

In a similar way, geometric decorrelation can also be reduced by bandwidth filtering, at a cost of resolution (Gatelli et al. 1994). This is possible because changing the look angle slightly is approximately equivalent to shifting the chirp frequency,

$$\Delta f \approx -\frac{c}{\lambda} \frac{\Delta \theta}{\tan(\theta - \alpha)}, \quad (9)$$

where c is the speed of light, λ is the wavelength, $\Delta \theta$ is the change in look angle, and α is the angle between the horizontal and the baseline vector. $\Delta \theta$ is proportional to the perpendicular baseline; thus, if the perpendicular baseline is too large, there is no overlapping bandwidth, resulting in total decorrelation. The perpendicular baseline at which this occurs is referred to as the *critical baseline*, which is about 1,100 m for ERS and Envisat satellites as an example.

Phase Unwrapping

Phase unwrapping is the process of estimating the difference in the number of whole phase cycles between an arbitrary reference pixel and every other pixel. Pictorially, this can be considered as counting the number of color fringes from the reference pixel (Fig. 3). The basic assumption of phase-unwrapping algorithms is that the phase field is generally sampled at above the Nyquist rate, so that the phase difference between neighboring pixels is generally less than half of a phase cycle. The basis then, for most algorithms, is to calculate the phase difference between neighboring pixels, wrap this into the interval between $-1/2$ and $1/2$ of a phase cycle, and then integrate these phase differences.

However, it is rarely the case across that this assumption holds across a whole interferogram, due to steep gradients and/or discontinuities in the topographic or deformation phase or due to decorrelation noise. In this case, the path taken in the integration step matters – the algorithm needs to avoid integrating between pixels where the phase difference is more than half of a cycle. Mathematically these can be considered as branch cuts. In order to place these branch cuts, an extra constraint is required, and for most algorithms this can be framed in terms of minimization of a weighted function of the residuals between the estimated unwrapped phase differences and the wrapped phase differences:

$$\sum_{i,j} w_{i,j}^{(x)} |\Delta\phi_{i,j}^{(x)} - \Delta\psi_{i,j}^{(x)}|^p + \sum_{i,j} w_{i,j}^{(y)} |\Delta\phi_{i,j}^{(y)} - \Delta\psi_{i,j}^{(y)}|^p, \quad (10)$$

where $\Delta\phi^{(x)}$ and $\Delta\psi^{(x)}$ are the unwrapped and wrapped phase differences, respectively, between pixels in the x direction, $\Delta\phi^{(y)}$ and $\Delta\psi^{(y)}$ are the equivalent in the y direction, and w are user-defined weights (Chen 2001). The summations are carried out in both x and y directions over all i and j , respectively. This is sometimes referred to as an L^p -norm objective function, although strictly speaking, to meet the condition of positive scalability, the sum must be raised to the power of $1/p$, and p must be greater than or equal to 1. However, for $p \geq 1$, the solution that minimizes this objective function also minimizes the L^p -norm.

Two common algorithms that are applied to solve phase-unwrapping problems are the branch-cut algorithm (Goldstein et al. 1988) and the minimum cost flow algorithm (Costantini 1998). In the former case, the algorithm seeks to minimize the total number of nonzero residuals, equivalent to setting $p = 0$ and $w_{i,j}^{(x)} = w_{i,j}^{(y)} = 1$. In the latter case, the algorithm seeks to minimize the weighted sum of the absolute value of the residuals, equivalent to $p = 1$.

The third well-established algorithm implements a statistical cost flow methods and seeks to find the most probable solution overall for any

given probability distributions allocated to each phase difference (Chen 2001). The probability distributions are assigned based on the statistics of various measures, such as correlation and amplitude.

A-InSAR

Displacements can be estimated more accurately by processing many images together, rather than the two image approaches described above. While the approach to conventional InSAR is reasonably standardized, there are many variations on A-InSAR algorithms. However, an overview of the main approaches is described in this section.

The simplest approach for combining many images is to sum or “stack” the unwrapped phase of many conventionally formed interferograms. The deformation signal reinforces, whereas other signals typically do not. However, this approach is only appropriate when the deformation is episodic or purely steady state, with no seasonal deformation. Even then it is not optimal, as non-deformation signals are reduced only by unweighted averaging rather than by optimized estimation.

Algorithms for time-series analysis of SAR data have thus been developed to better address the issues facing conventional InSAR; decorrelation is tackled by using phase behavior in time to select pixels for which decorrelation noise is minimized, and non-deformation signals are estimated by a combination of modeling and filtering of the time series. These time-series algorithms fall into two categories, the first being persistent scatterer InSAR, which targets pixels whose scattering properties remain consistent both in time and from variable look directions, and the second being a more general small baseline approach. Because the two approaches are optimized for resolution elements with different scattering characteristics, they are complementary, and techniques that combine both approaches are able to extract the signal with greater coverage than either method alone (Hooper 2008).

Persistent Scatterer InSAR

Decorrelation is caused by the contributions from scatterers within a resolution element summing differently. This can be due to a relative movement of the scatterers, a change in the looking direction of the radar platform, or the appearance or disappearance of scatterers, as in the case of snow cover. If one scatterer returns significantly more energy than other scatterers within a resolution element, however, decorrelation is reduced. This is the principle behind a “persistent scatterer” (PS) pixel (sometimes referred to as a “permanent scatterer”). Urban environments typically contain many of these dominant scatterers, for instance, roofs oriented such that they reflect energy directly back to the sensor and perpendicular structures that lead to a “double bounce,” where energy is reflected once from the structure and once from the ground, returning directly back to the sensor. Dominant scatterers can also occur in areas without man-made structures, e.g., appropriately oriented rocks, but there are fewer of them, and they tend to be less dominant.

PS algorithms operate on a time series of interferograms all formed with respect to a single “master” SAR image (Fig. 4a). The first step in the processing is the identification and selection of the usable PS pixels. There are two approaches to this; the first relies on modeling the deformation in time (Kampes 2005), and the second relies

on the spatial correlation of the deformation (Hooper et al. 2007). In the first approach, the phase is unwrapped during the selection process, by fitting a temporal model of evolution to the wrapped phase difference between pairs of nearby PS, although later enhancements to the technique allow for non-model-based improvements to the unwrapping. In the second approach a phase-unwrapping algorithm is applied to the selected pixels without assuming a particular model for the temporal evolution, other than it should be generally smooth.

In both approaches, deformation phase is then separated from atmospheric phase and noise by filtering in time and space, the assumption being that deformation is correlated in time, atmosphere is correlated in space but not in time, and noise is uncorrelated in space and time. Additional approaches to reducing atmospheric phase (section “Atmospheric Phase”) can be applied prior to the filtering. In comparative studies between the two PS approaches, estimates for the deformation estimates tend to agree quite well, but the second approach tends to result in better coverage, particularly in rural areas, which is where most volcanoes are sited.

The result of PS processing is a time series of displacement for each PS pixel, with much reduced noise terms (Fig. 5). The technique also has the advantage of being able to associate the deformation with a specific scatterer, rather than

InSAR and A-InSAR: Theory, Fig. 4 An example baseline plot for (a) the persistent scatterer method and (b) the small baseline approach. Red circles represent SAR images and blue lines indicate the interferograms that

are formed. Perpendicular baseline refers to the component of the satellite separation distance that is perpendicular to the look direction and is proportional to the difference in look angle

InSAR and A-InSAR: Theory, Fig. 5 Average displacement rates (mm/year) for Venice using a persistent scatterer approach applied to COSMO-SkyMed data from 2008 to 2011. The image background is an

aerophotograph acquired in 2009. Negative values indicate settlement, positive mean uplift (Modified after Tosi et al. (2013))

a resolution element of dimensions dictated by the radar system, usually on the order of many meters. This allows for very high-resolution monitoring of infrastructure.

Small Baseline InSAR

A drawback of the PS technique for many applications is that the number of PS pixels in rural environments may be limited. For non-PS pixels, containing no dominant scatterer, phase variation due to decorrelation may be large enough to obscure the underlying signal. However, by forming interferograms only between images separated by a short time interval and with a small difference in look direction, decorrelation is minimized, and for some resolution elements can be small enough that the underlying signal is still detectable. Pixels for which the phase decorrelates little over short time intervals are the targets of small baseline methods.

Interferograms are formed between SAR images that are likely to result in low

decorrelation noise, in other words, those that tend to minimize the difference in time and look direction (Fig. 4b). As it is not possible to minimize both of these at once, assumptions are made about their relative importance, based on the scattering characteristics of the area of interest.

The interferograms can then be multilooked to further decrease decorrelation noise, either using a standard windowing approach or by using amplitude to identify pixels with similar scattering characteristics (Ferretti et al. 2011). However, there may be isolated ground resolution elements with low decorrelation properties that are surrounded by elements that decorrelate highly, such as a small clearing in a forest, for which multilooking will increase the noise. Therefore, algorithms have been developed that operate at full resolution (Hooper 2008), with the option to reduce resolution later in the processing chain by selective multilooking.

Pixels are selected based on their estimated coherence in each of the interferograms, using either standard ensemble coherence estimation or enhanced techniques in the case of

InSAR and A-InSAR: Theory, Fig. 6 Cumulative line-of-sight displacement over Eyjafjallajökull Volcano, Iceland, from 18 June 2009 to 01 September 2010, processed using a small baseline approach (track 132 ascending mode). The co-eruptive interval includes a flank eruption, during which there was very little deformation, and the later summit eruption, during which the volcano deflated. The background is shaded topography. The hole in the data is due to ice and snow cover. *Black dots* are earthquake epicenters for each epoch (Icelandic Meteorological Office) (Modified after Pinel et al. (2014))

full-resolution algorithms. The phase is then unwrapped either spatially in two dimensions using standard approaches or using the additional dimension of time in three-dimensional approaches (Pepe and Lanari 2006; Hooper 2010). At this point the phase is inverted to give the phase at each acquisition time with respect to a single image, using least squares, singular value decomposition, or minimization of the L^1 -norm (Fig. 6).

Separation of deformation and atmospheric signals is achieved by filtering the resulting time series in time and space, as in the PS approach. Alternatively, if an appropriate model for the evolution of deformation in time is known, the different components can be directly estimated from the small baseline interferograms (Biggs et al. 2007).

Summary

InSAR is a powerful tool for high-resolution measurement of surface heights with meter scale accuracy, surface displacements with cm accuracy, and surface velocities with mm/year accuracy. Spatial resolution varies from under a meter to tens of meters, depending on the sensor and mode of operation.

Studies of ground deformation, in particular, have benefitted from more than 20 years of continuous satellite SAR observations. This archive is about to be enhanced by new satellite SAR missions, in addition to the growing application of ground-based and airborne SAR systems, which will provide improved temporal and spatial resolution, broader geographic coverage, and better availability to the scientific community.

The main advantage of InSAR remains its ability to collect useful imagery without regard to the time of the day or weather conditions and to record surface deformation on the scale of mm/year over broad regions with a spatial resolution on the order of meters. InSAR applications to seismology can thus be both regional in scope (entire tectonic regions) and highly focused (individual buildings).

Introduction

Building sustainable and resilient communities against extremely large earthquakes is a global and urgent problem in active seismic regions. A catastrophic earthquake and its cascading events, such as tsunami and fire, affect multiple structures and infrastructure simultaneously and have far-reaching economic impact across various sectors in a complex manner. Incurred seismic damage includes loss of life and limb, direct financial loss to building properties and lifeline facilities (capital stock), and indirect loss due to the ripple effects of the direct loss across regional and national economies. All these consequences are revealed in an abrupt reduction of gross domestic product (GDP) for national economy and of stock indices and prices for companies.

One of such devastating events was the 2011 M_w 9.0 Tohoku earthquake in Japan among recent earthquake disasters around the world (e.g., 2004 Sumatra, 2008 Wenchuan, and 2010 Haiti earthquakes). For instance, a post-earthquake economic impact analysis of the 2011 Tohoku earthquake by Kajitani et al. (2013) revealed that the economic impact was significant not only in directly affected regions but also in regions outside the damaged areas due to disruptions of supply chains and domestic/international trade networks. The financial consequences of

Insurance and Reinsurance Models for Earthquake,

Fig. 1 Earthquake-related economic and insurance losses

such major earthquakes have long-term impacts (e.g., stagnant regional economy due to loss of market share). Households in disaster areas suffer from loss of asset and income; recovery from earthquakes can be extremely difficult, and financial public support/aid from governments and municipalities is not sufficient to cover the loss. Moreover, catastrophic earthquakes impose tremendous financial stress on insurers and reinsurers underwriting earthquake insurance policies (Grace et al. 2003; Muir-Wood 2011). The CATDAT damaging earthquakes database (Daniell et al. 2011) reports that the 2011 Tohoku earthquake and tsunami, the 2010–2011 Christchurch (New Zealand) sequences, and the 2010 Maule (Chile) earthquake rank in the top 10 list for the highest insured loss since 1900, exceeding \$10 billion. Figure 1 shows a history of estimated economic and insurance losses since 1950 according to the CATDAT database. The CATDAT values are adjusted based on the Hybrid Natural Disaster Economic Conversion Index (HNDECI), which takes into account temporal as well as geographical variation of consumer price indices, wage and low-wage indices, exchange rate, and other factors to facilitate the uniform and consistent comparison of the disaster

consequences (Daniell et al. 2011). The figure illustrates the significant magnitude of earthquake catastrophes, which is caused by a combination of physical hazard, exposure, vulnerability, and socioeconomic factors of the interconnected economies around the world.

Recent catastrophes have highlighted that the financial consequences to stakeholders can be significant. It is necessary to enhance the capability of dealing with such low-probability high-consequence (LP-HC) events through integrated seismic risk management by combining hard and soft disaster risk reduction (DRR) measures. Generally, hard and soft measures are complementary, and such integrated DRR solutions are robust against unforeseen and uncertain events. An important difference between hard risk mitigation measure (e.g., seismic retrofitting) and soft risk transfer measure (e.g., insurance) is that the former physically reduces the actual extent of seismic damage, while the latter transfers the incurred loss to a third party based on a pre-agreed risk-sharing scheme. Because the recovery process is (highly) nonlinear and dependent on various post-disaster situations (e.g., prolonged business interruption may result in loss of share in a competitive market), earthquake

insurance has the effects of accelerating the recovering process.

This entry is focused upon earthquake risk management using insurance and reinsurance. Earthquake insurance is a form of loss indemnity contract, where an insurer pays policyholders in the event of a major earthquake that causes damage to their properties. Insurance smoothes out the policyholder's wealth at different contingent states (i.e., no earthquake versus major earthquake), while an insurer underwrites policyholders' potential seismic risks collectively in exchange for insurance premium. Because an insurer may face an unacceptable level of insolvency risks due to catastrophic earthquakes, the risks may be transferred to a reinsurer, i.e., reinsurance refers to a risk-sharing contract between insurer and reinsurer. A reinsurer usually has greater capacity to absorb large financial shocks and helps diversify the seismic risks geographically and across different perils. It is also important to recognize the critical role of governments in national earthquake insurance programs, as they back up some layers of potential earthquake loss. An overview of the earthquake insurance and reinsurance system is given in the "[Insurance and Reinsurance System](#)" section, while a summary of existing insurance systems in major seismic countries is provided in the "[Existing Insurance Systems Around the World](#)" section.

The nature of catastrophic earthquake risks, i.e., correlated loss generation, poses major challenges in achieving the effective diversification of collective seismic risk and may overwhelm the financial capacities of insurers and reinsurers. To avoid the potential insolvency and major constraint in business operation, utilizing alternative risk transfer (ART) tools, such as earthquake catastrophe (CAT) bonds, may be considered (Lalonde 2005; Cummins 2008). Another concern of providing earthquake loss coverage includes adverse selection and moral hazard (Grace et al. 2003), which are influenced by various factors, such as risk perception, asymmetrical information, (cognitive) psychology, framing, personal experience, etc. (Johnson et al. 1993;

Palm 1995; Kunreuther 1996; Kahneman 2003; Viscusi and Evans 2006). A summary of these challenges is provided in the "[Challenges in Insuring Low-Probability High-Consequence Risks](#)" section.

Approaches for modeling (catastrophe) insurance and reinsurance, adopted in different academic disciplines, are diverse, as their purposes and focuses are often different. Economists formulate insurance purchase problems as rational decision-making under uncertainty and examine arrangements for optimal insurance (Mossin 1968; Ehrlich and Becker 1972; Schlesinger 2000). On the other hand, behavioral economists and psychologists take a flexible view on decision-making problems by incorporating cognitive aspects of human beings (Johnson et al. 1993; Kahneman 2003; Viscusi and Evans 2006). In actuarial sciences, the problems are defined mathematically by capturing the key elements of the stochastic insurance risk processes (Rolski et al. 1999; Cossette et al. 2003; Goda and Yoshikawa 2012), which are not modeled in economic analyses. In earthquake engineering, earthquake CAT models that incorporate the state of the art in engineering seismology and earthquake engineering by taking into account uncertainties are used to assess the financial seismic risk quantitatively (Bommer et al. 2002; Dong and Grossi 2005; Wesson et al. 2009; Asprone et al. 2013; Yucemen 2013). Moreover, an extended approach considers the applications of actuarial/engineering methods in the context of economical decision-making problems (e.g., CAT models are embedded into the expected utility framework for insurance decision-making). Figure 2 depicts an overview of insurance models, involving various disciplines, such as seismology, earthquake engineering, statistics, economics, actuarial sciences, and psychology. Key features of different approaches are described in the "[Insurance and Reinsurance System](#)" section. Specifically, the "[Earthquake Catastrophe Model](#)" section discusses applications of the CAT models to earthquake insurance; the "[Actuarial and Financial Insurance Model](#)" section presents stochastic modeling of insurance

Insurance and Reinsurance Models for Earthquake,

Fig. 2 Overview of risk models for earthquake insurance decision-making

risk processes; and the “[Economic Insurance Model](#)” section gives a summary of methods based on economics and expected utility decision theories. Finally, in the “[Integrated Earthquake Risk Management](#)” section, the role of insurance and reinsurance in the context of integrated earthquake risk management is discussed by broadening the scope of this entry (e.g., earthquake risk premium discount as incentive to promote seismic retrofitting; Kleindorfer et al. 2005; Michel-Kerjan et al. 2013).

Insurance and Reinsurance System

This section gives an overview of current insurance-reinsurance systems for earthquake risk coverage. In the “[Insurance and Reinsurance System](#)” section, key stakeholders as well as their interrelationships are defined. Subsequently, main features of the current insurance systems in major seismic regions/countries are described in the “[Existing Insurance Systems Around the World](#)” section. Subsequently, issues and challenges in insuring LP-HC earthquake events are discussed in the “[Challenges in Insuring Low-Probability High-Consequence Risks](#)” section.

Insurance-Reinsurance System

A generic representation of insurance-reinsurance system for managing earthquake risks is shown in Fig. 3. The identified key stakeholders are policyholders (e.g., owners of properties and enterprises), insurers operating at local/regional/national levels, reinsurers dealing with risk diversification at international scale, insurance commissioners/governments, rating agencies as auditor, and capital markets where investors gather for financial transactions.

Policyholders, Insurers, and Governments:

In the event of a major destructive earthquake, policyholders may suffer from seismic damage to their properties and assets and incur financial loss. To mitigate the potential financial impact, they may insure such risks by purchasing earthquake insurance coverage. Alternatively, they have options to mitigate the earthquake damage by adopting physical mitigation measures, such as seismic retrofitting and upgrading. Acceptance of earthquake insurance and/or physical risk mitigation measures largely depends on the risk perception of property owners and on the type of properties (e.g., home versus business). Issues related to risk perception and acceptance of earthquake protection are discussed in the “[Challenges](#)

Insurance and Reinsurance Models for Earthquake, Fig. 3 Overview of an insurance-reinsurance system

in Insuring Low-Probability High-Consequence Risks” section.

Insurers offer earthquake risk coverage, usually as part of other insurance (e.g., fire insurance and multi-peril coverage). Depending on country and property type, purchase of earthquake coverage is compulsory or voluntary. A primary insurer collects insurance premiums from policyholders and reimburses incurred seismic loss based on a pre-agreed policy upon the occurrence of a damaging earthquake. The insurance premium P_I typically consists of three components:

$$P_I = P_{\text{pure}} + P_{\text{risk}} + C_{\text{transaction}} \quad (1)$$

where P_{pure} is the pure premium and is the expected cost of the ceded risks (i.e., fair price for the risk coverage), P_{risk} is the risk premium and is determined based on various factors (e.g., insurer’s capital reserve, reinsurance price/availability, and regulatory requirements), and $C_{\text{transaction}}$ is the transaction cost related to marketing, monitoring, and claim settlement. As both P_{risk} and $C_{\text{transaction}}$ are greater than zero and not negligible (particularly for earthquake coverage, P_{risk} can be large, in comparison with P_{pure}), risk-neutral owners, who make decisions based on the expected values without considering variability of the consequences, regard insurance coverage

as overpriced and unfavorable economically. Thus only risk-averse owners, who take into account uncertainties of the consequences, may seek insurance coverage. In cases owners are affected/biased due to their risk perception (e.g., overestimation of potential consequences), earthquake insurance coverage may or may not be attractive for them. Another important aspect to note is that insurance has additional benefits of providing financial liquidity with policyholders in post-disaster situations. For example, a policyholder who has purchased a property with a mortgage may face liquidity constraints after a major earthquake that damages the property severely; the policyholder may not be able to borrow money to recover the loss immediately after the earthquake, because the collateral (i.e., property) is damaged/lost and there is an outstanding mortgage repayment. In such cases, insurance coverage is beneficial in enhancing financial resilience against major shocks.

The policy (payout) function of an insurance contract F_{payout} for the earthquake damage cost C_{EQ} takes the following form:

$$F_{\text{payout}}(C_{EQ}) = \begin{cases} 0 & C_{EQ} \leq D \\ \gamma(C_{EQ} - D) & D < C_{EQ} < L \\ \gamma(L - D) & C_{EQ} \geq L \end{cases} \quad (2)$$

where D , L , and γ are the deductible, limit (cap), and coinsurance factor, respectively. The deductible is the starting loss value of the insurance payout and is usually specified in terms of total insured value. The limit is the maximum loss value of the insurance payout, expressed in terms of total insured value. From insurers' viewpoint, the deductible is useful for reducing transaction costs related to small claims, while the upper limit is effective in avoiding very large claims (critical for their solvency). The coinsurance factor specifies the proportional share of an incurred seismic loss between a policyholder and an insurer; this helps suppress the problem related to moral hazard. For instance, consider that an owner has a house of total value equal to \$200,000 and has purchased earthquake insurance coverage with $D = 10\%$, $L = 80\%$, and $\gamma = 90\%$. In cases where the owner incurs seismic losses of \$60,000 and \$180,000, he/she will receive \$36,000 and \$126,000, respectively.

The reinsurance policy has essentially the same structure as primary insurance and is mainly classified into two types: pro rata contract and excess-of-loss contract. In pro rata contracts, an insurer and reinsurer share the risk proportionally (similar to coinsurance), while in excess-of-loss contracts, a reinsurer provides coverage in a specific layer between attachment point and exhaustion point (similar to deductible and limit).

The sales of earthquake risk coverage are often regulated by statutory bodies, such as insurance commissioners. The main reasons are that earthquake insurance, unlike other liability insurance, tends to be *public* (i.e., protection against involuntary risks) and after major earthquake disasters, governments and states may intervene to provide public support to the affected people (e.g., monetary gift and special loan programs). Although, in reality, such disaster relief activities are inevitable (which are funded by tax and borrowing), it is desirable to minimize post-disaster intervention (ex ante subsidies) as this may discourage DRR efforts prior to earthquakes (Kunreuther 1996). This is referred to as charity hazard. It has been demonstrated that DRR

measures are often cost-effective, in comparison with situations without DRR (Kleindorfer et al. 2005; Michel-Kerjan et al. 2013).

Insurers, Reinsurers, Auditors, Regulators, and Capital Markets: The basic principle of insurance portfolio management is the law of large numbers; with the increase in the number of policies, variability of aggregate claims of a portfolio becomes small, and thus actual total loss approaches the expected loss value (which increases with the number of policies). In simple terms, the financial risk becomes more predictable. It is important to recognize that this theory is applicable to *independently distributed events* (e.g., car insurance), while the earthquake risks are both spatially and temporally correlated. Insurers may experience a devastating surge of seismic loss claims in a disaster-hit region and face the possibility of insolvency. Therefore, insurers need to diversify their earthquake exposures geographically.

A conventional approach for catastrophe risk transfer is reinsurance by global reinsurers (Munich Re, Swiss Re, etc.) and governments (Fig. 3). A notable functionality of governments as reinsurer is their ability to borrow money by issuing bonds; this achieves temporal diversification of earthquake risks. Although reinsurers have greater risk-bearing capacities than insurers and achieve geographical risk diversification through their national/global portfolios, the potential size of the catastrophic earthquakes can be significant and their default risk is not zero. Because of this, reinsurers charge quite high risk premium to insurers and seek alternative means for risk transfer (Cummins 2008), which in turn affects the risk premiums for primary insurance coverage. Reinsurers also utilize retrocession, i.e., risk transfer from a reinsurer to another reinsurer to reduce the impact of peak risks. Recently, financial market instruments, so-called insurance-linked securities, become available through capital markets (Grace et al. 2003; Lalonde 2005) and have been used more frequently by insurers, reinsurers, and governments/states (Cummins 2008; see also recent market review articles/reports published by Munich Re and Swiss Re). The emerging tools

Insurance and Reinsurance Models for Earthquake, Fig. 4 Loss diagram for stakeholders, insurer, reinsurer, and capital market

take advantage of much greater financial capacity of capital markets, covering high-loss layers of insurance-reinsurance portfolios. Since earthquake insurance is an integrated part of catastrophe risk management, insurance commissioners, on behalf of governments, regulate the solvency status and insurance policy/pricing of insurers. A high insolvency risk is not acceptable for public earthquake insurance systems. For monitoring the financial status of the earthquake risk underwriters, credit rating agencies (e.g., Standard & Poor's and Moody's) send useful signals to involved parties on their catastrophe exposures. However, the amount of correlations created by retrocession is not transparent to regulators and auditors.

A useful tool for visualizing the composition of catastrophe risk diversification by different stakeholders is the loss diagram (Dong and Grossi 2005). It displays how the total loss is divided and covered by involved parties. Figure 4 shows a hypothetical loss diagram for aggregate seismic loss; in addition, a so-called exceedance probability (EP) curve of the entire portfolio is included. In the diagram, policyholders retain seismic loss up to \$10 million (i.e., deductible for the entire portfolio) and seismic loss

exceeding \$50 million (i.e., insurable limit). The loss layer between \$10 and \$40 million is covered by an insurer and a reinsurer; the first \$10 million layer is solely covered by the primary insurer, while the next \$20 million layer is shared by the excess-of-loss reinsurance with proportional rate of 0.2 (i.e., \$20 and \$40 million are the attachment and exhaustion points of the reinsurance contract, respectively). The high-loss layer between \$40 and \$50 million is ceded to capital markets via CAT bonds/securities.

Existing Insurance Systems Around the World

Earthquake risks are prevalent globally. Countries located near the plate boundaries constantly experience major seismic and volcanic activities. One notable example is the Ring of Fire, or the circum-Pacific seismic belt, which hosts the majority of large earthquakes around the world. The circum-Pacific countries include Chile, Peru, Mexico, the USA (California and Alaska), Japan, Taiwan, the Philippines, Indonesia, and New Zealand, while other major seismic countries are Iceland, India, Iran, Italy, Pakistan, and Turkey. In some of these countries, earthquake insurance systems have been established and operated (NLIRO 2008; OECD 2008). This section

provides a brief summary of existing insurance systems in California (USA), Iceland, Japan, Mexico, New Zealand, Taiwan, and Turkey. Table 1 compares the main features of different insurance systems. In addition, a brief description of natural catastrophe coverage in the EU is included.

California (USA): In California, earthquake insurance coverage had been offered privately since early twentieth century. Currently, the privately funded, state-run California Earthquake Authority (CEA), which was established in 1996 in the aftermath of the 1994 Northridge earthquake, provides earthquake insurance coverage to homeowners; policies can be obtained incidental to fire insurance (optional). Insurer's CEA membership is voluntary and member companies satisfy the mandatory offer law for selling the CEA policy. It is noteworthy that the CEA is not backed up by the State of California. The payable limit of the CEA is about US\$ 100 million; if this amount is exceeded, the claim repayments are proportionally reduced. The policy covers damage and loss due to earthquakes. The premium rates range from 0.036 % to 0.90 %, depending on zip code, structural type, built year, and number of stories. A relatively high deductible of 15 % is specified (10 % can be selected). Policyholders can insure residential properties up to the total insurance value, while they can choose the level of coverage for content (e.g., US\$ 5,000–100,000) and incidental expenses (e.g., US\$ 1,500–15,000).

Iceland: The state-owned Iceland Catastrophe Insurance (ICI), which was established in 1975 after the 1973 Mt. Heimaey volcanic eruptions, provides catastrophe coverage for natural hazards including volcanic eruptions, earthquakes, landslides, snow avalanches, and floods. The participation is compulsory, incidental to fire insurance, and covers direct loss to buildings, content, and lifelines. The deductible is 5 % for each loss. The premium rate for properties and content is 0.025 %, while that for lifelines is 0.02 %. The ICI is liable up to 1 % of the total insured capital; if this amount is exceeded, the claim repayments are proportionally reduced.

Japan: The government-endorsed Japan Earthquake Reinsurance Company (JERC), which was established in 1966 after the 1964 Niigata earthquake, plays a major role in promoting earthquake insurance for residential buildings. The purchase is incidental to fire insurance and is not mandatory (thus the penetration rate is not so high). Primary insurers sell policies and collect fees from policyholders; the covered loss is retained by the JERC, government, and private insurers. The aggregate limit of the indemnity for earthquake insurance is JPY 6.2 trillion; if this amount is exceeded, the claim repayments are proportionally reduced. The policyholder can obtain earthquake coverage up to about 30–50 % of the total insured value under fire insurance policy; in addition, the maximum insured amount is limited to JPY 50 million for buildings and JPY 10 million for movables, respectively. There is a discount mechanism of premiums to encourage seismic risk mitigation; for instance, properties with base isolation are granted for 30 % discount, and certified properties which meet the current seismic design requirements are granted for 10 % discount. Other cases include “buildings constructed after 1981 (when the new seismic design code was implemented in Japan),” and “certified buildings according to the seismic grading system.”

Mexico: Earthquake insurance in Mexico is mainly provided by private insurers, under the regulation by the Comision Nacional de Seguros y Fianzas (CNSF). The major seismic event that led to adoption of earthquake insurance was the 1985 Michoacan earthquake. The purchase is optional and is often accompanied by fire insurance. The insurance covers damage and loss of buildings and movables due to earthquakes and volcanic eruptions. The premium rates vary widely, depending on occupancy type, number of stories, and geographical region. Typical values of deductible are 2–5 %. In addition to private earthquake insurance, the government-supported Natural Disasters' Fund, which was created in 1996, provides financial support to the recovery/restoration of impaired infrastructure and to the disaster victims.

Insurance and Reinsurance Models for Earthquake, Table 1 Comparison of earthquake insurance systems in different countries (NLIRO 2008; OECD 2008)

Country	Insurance commissioner	Participation method	Coverage	Rate	Insured amount and limit	Payable claim amount	Role of primary insurers
California (USA)	California Earthquake Authority (CEA)	Incidental to fire insurance (optional)	Residential building and content; damage due to earthquakes	0.036–0.90 %; 19 classes (zip code); 8 classes (structural type and built year); 2 classes (story number)	Building: total insurance value; content, US\$5,000–100,000; incidental expense, US\$ 1,500–15,000; deductible, 15 %	US\$ 96 million per event	Sales, fee collection, certificate issuance, remittance, and assessment
Iceland	Iceland Catastrophe Insurance (ICI)	Incidental to fire insurance (compulsory)	Building, content, and lifelines; damage due to earthquakes, volcanic eruptions, landslides, avalanches, and floods	0.025 % for buildings and content; 0.02 % for lifelines	Deductible, 5 % of each loss (minimum deductible – ISK 85,000 for building, ISK 20,000 for content, and ISK 750,000 for lifelines)	1 % of the total insured capital	Sales, fee collection, and certificate issuance
Japan	Japan Earthquake Reinsurance Company (JERC)	Incidental to fire insurance (optional)	Residential building and movables for living; damage due to earthquakes, volcanic eruptions, and tsunamis	0.05–0.313 %; 8 classes (structural type and geographical region)	30–50 % of the total insured value under fire insurance policy (maximum insured amount is up to JPY 50 million for buildings and JPY 10 million for movables); deductible, 3 % (building) and 10 % (movables)	JPY 6.2 trillion	Sales, fee collection, certificate issuance, damage assessment, and insurance underwriting

Mexico	Private insurers regulated by Comision Nacional de Seguros y Fianzas (CNSF)	Optional	Residential building, commercial/ industrial building, and movables for living; damage due to earthquakes and volcanic eruptions	0.018–0.356 % for residential building; 12 classes (geographical region); 0.028–0.726 % for commercial/industrial building; 12 classes (geographical region) and 2 classes (story number)	Total insurance value (but some upper limits [70–90 %] may be applied in high-seismic regions); deductible, 2–5 % (depending on geographical region)	N/A	Sales, fee collection, certificate issuance, damage assessment, and insurance and underwriting
New Zealand	Earthquake Commission (EQC) – EQCover	Incidental to fire insurance (compulsory)	Residential building, content, and land; damage due to earthquakes, landslides, volcanic eruptions, and tsunamis	0.05 % for residential building	Building, NZ\$ 100,000; content, NZ\$ 20,000; land, total insurance value Deductible, 1 % (building), NZ\$ 200 (content), and 10 % (land, maximum deductible is set to NZ\$ 5,000)	All claims to be repaid (backed up by the government)	Sales and fee collection
Taiwan	Taiwan Residential Earthquake Insurance Fund (TREIF)	Incidental to fire insurance (compulsory)	Residential building; damage due to earthquakes	0.122 %	Building, TW\$ 1.2 million; contingent expenses, TW\$ 180,000; no deductible	TW\$ 60 billion	Sales
Turkey	Turkish Catastrophe Insurance Pool (TCIP)	Compulsory	Building; damage due to earthquakes	0.044–0.55 %; 15 classes (structural type and geographical region)	TRY110,000 (in Turkish lira [TRY]); deductible, 2 %	EUR 1 billion (from reinsurance)	Sales, fee collection, certificate issuance, and damage assessment

New Zealand: The government-owned Earthquake Commission (EQC) provides natural disaster insurance (EQCover) to homeowners in New Zealand. The EQC was established in 1944 after the devastating 1942 Wairarapa earthquakes. The participation is incidental to fire insurance and is automatic/compulsory. The contract covers damage and loss of residential properties, content, and land due to earthquakes, landslides, volcanic eruptions, and tsunamis. The premium rate is 0.05 %. The insured amount is limited to NZ\$ 100,000 for buildings and NZ\$20,000 for content, respectively. The deductible is set to NZ\$ 200 or 1 % of the loss for residential properties, NZ\$200 for content, and the greater of NZ\$ 500 or 10 % of the insured loss for land, with the maximum deductible of NZ\$ 5,000. In addition to the EQCover, private insurers offer natural disaster damage extension, which can insure commercial buildings (variable rates depending on geographical region, structural type, built year, and number of stories).

Taiwan: The government-endorsed Taiwan Residential Earthquake Insurance Fund (TREIF) operates the earthquake insurance program in Taiwan. TREIF was established in 2002 in the aftermath of the 1999 Chi-Chi earthquake. The policy is incidental to fire insurance and its purchase is compulsory. The insurance covers damage and loss of residential properties due to earthquakes. The upper limit of the repayment per household is TW\$ 1.2 million for residential properties and TW\$ 180,000 for contingent expenses, respectively. The premium rate is 0.122 %. The total amount of the payable claims is TW\$ 60 billion.

Turkey: The state-owned Turkish Catastrophe Insurance Pool (TCIP) was created after the 1999 Izmit earthquake to reduce catastrophe earthquake exposure to the government. The owners of residential properties within municipality boundaries are obliged to take earthquake insurance coverage, which insures damage and loss due to earthquakes. The premium rates range from 0.044 % to 0.55 %, depending on structural type and geographical region. The maximum

insured limit is TRY 110,000 and the deductible is 2 %. Currently, as the financial status of the TCIP is not sufficient, it cedes a large amount of its risks to international reinsurers. Note that commercial and industrial properties as well as residential properties in rural areas can be insured on a voluntary basis.

EU Countries: Porrini and Schwarze (2012) classify variable insurance schemes for natural catastrophe coverage (including earthquakes for some countries) in EU member states into five categories: (1) regional public monopoly insurer of natural hazards guided by statutory provisions and public consultation processes; (2) compulsory insurance for all natural hazards; (3) compulsory inclusion of natural hazards into general house ownership insurance; (4) free-market natural hazard insurance with ad hoc governmental relief programs; and (5) taxpayer-financed governmental relief funds. The Netherlands, Denmark, and Switzerland have adopted Schemes 1 and 2; France and Spain have used Schemes 2 and 3; the UK has adopted Schemes 3 and 4; Germany has followed Scheme 4; and Poland, Italy, and Austria have adopted Schemes 4 and 5. These schemes suppress insurance-related problems, such as adverse selection, moral hazard, and charity hazard, differently. For instance, Scheme 1 can be used to mitigate all three issues, whereas Schemes 2 and 3 can deal with adverse selection and charity hazard effectively but may be susceptible to moral hazard. Effectiveness of Schemes 4 and 5 is limited to avoiding charity hazard and adverse selection, respectively. It is noteworthy that the selection of a suitable scheme has important influence on how risk mitigation and (financial) risk management are implemented. Furthermore, insurance penetration rates for earthquake coverage in Europe are unevenly distributed among member states of the EU (Maccaferri et al. 2011). Notably, many earthquake-prone countries (e.g., Italy, Greece, Romania, Spain, and Portugal) show rates below 10 %, although high maximum losses within the past 20 years have been experienced (e.g., Greece, 2.1 % in 2010 GDP value, and Italy, 0.6 % in 2010 GDP value).

Challenges in Insuring Low-Probability High-Consequence Risks

Risk perception has major influence on decision-making processes regarding the adoption of earthquake insurance (Kunreuther 1996). Facing LP-HC risks, home and business owners may have diverse opinions on the potential magnitude of earthquake consequences. Therefore, appreciation of benefits of earthquake insurance coverage varies significantly, depending on personal characteristics (e.g., optimistic or pessimistic), proximity to physical hazards (e.g., living near a major fault), previous experience with earthquakes, and socioeconomic/demographic profiles, such as age, gender, income, and education (Palm 1995). Another important aspect influencing insurance-related decisions is cognitive limitation of human beings (Kahneman 2003). It is well known that people are affected by framing (Johnson et al. 1993) and have difficulties in estimating very low probabilities (Viscusi and Evans 2006). An example of framing is that a factory owner who is considering earthquake insurance for financial protection is likely to take insurance if he/she is told that the chance of experiencing major earthquake damage is 1 in 5 over the entire period (20 years), rather than the chance of such an event is 1 in 100 per year. Therefore, even when the overall premium is reasonably priced, not many stakeholders voluntarily purchase earthquake risk coverage.

Two known issues in offering insurance coverage are moral hazard and adverse selection (note: they are applicable to not only catastrophe earthquake but other more common types). Moral hazard refers to a case where more risky situations (i.e., increase in chances of experiencing loss and/or increase in the extent of loss) are created by the behavior of a stakeholder. An example of moral hazard is that a policyholder, after a damaging earthquake, may cause additional damage to his/her property to receive insurance repayment (when the incurred loss is relatively minor and is near the threshold of deductible). On the other hand, adverse selection refers to a situation where an insurer cannot distinguish between stakeholders having lower and

higher earthquake risk potential. In such cases, the insurer cannot charge appropriate insurance premiums that are commensurate with the risks. For instance, if an insurer charges a flat rate for all homeowners in a specific geographical region, earthquake insurance is more attractive for those who live in seismically more vulnerable houses (e.g., non-ductile old construction). This leads to higher-risk exposure for the insurer than it is originally expected and may result in increasing the premium rate (i.e., adverse selection spiral can occur). One of the main causes of moral hazard and adverse selection is the information asymmetry between an insurer and a policyholder. The private information that the stakeholder has on his/her property is not entirely accessible to the insurer; in such cases, the stakeholder may have an incentive to behave inappropriately from the insurer's perspective.

To alleviate the effects due to moral hazard and adverse selection, introducing pro rata share of the risks and differentiating the rates according to physical parameters related to seismic hazard and vulnerability of the covered properties (e.g., geographical region, structural type, built year, and number of stories) are useful (see Table 1). Other proactive ways to avoid adverse selection and encourage physical DRR measures are to implement an effective incentive scheme in determining insurance premium rates (e.g., Japanese insurance system).

Insurance and Reinsurance Models

This section gives an introduction to a wide range of earthquake insurance and reinsurance models that have been developed and applied in different academic fields (Fig. 2). The “[Earthquake Catastrophe Model](#)” section provides a brief summary of earthquake CAT modeling and quantitative risk metrics. The key requirements of viable CAT models are mentioned. Next, actuarial/financial insurance models are presented in the “[Actuarial and Financial Insurance Model](#)” section. Subsequently, economic insurance models are summarized in the “[Economic Insurance](#)

Model” section to give an overview of the decision-making processes for policyholders (demand) and for insurers (supply).

Earthquake Catastrophe Model

Earthquake CAT modeling is an integrated process of conducting numerical simulations of earthquake occurrence, ground motion prediction, damage assessment, and seismic loss calculation. It typically involves: (i) inventory/exposure database, (ii) hazard characterization, (iii) structural vulnerability assessment, and (iv) loss estimation and insurance portfolio analysis. The output for the CAT models is the probability distribution of estimated seismic loss for a building/infrastructure portfolio (i.e., EP curve). There are a variety of different methods and models used for earthquake insurance risk analysis in research and in practice (e.g., Bommer et al. 2002; Asprone et al. 2013; Yucemen 2013). Current challenges of the CAT modeling include the validation of the CAT models using scarce loss data and dealing with rapidly changing exposure data (particularly for developing countries) and the incorporation of multiple concurrent hazards and risks, such as tsunamis, aftershock, liquefaction, landslide, and fire, within a unified analytical/computational framework.

A stochastic earthquake catalog method (e.g., Goda and Yoshikawa 2012) starts with a regional probabilistic seismic hazard model and generates a synthetic earthquake catalog using Monte Carlo sampling techniques. For each earthquake in a catalog, seismic vulnerability assessment and loss estimation are carried out using fragility curves and damage-loss functions. A fragility curve evaluates conditional probability of exceeding a certain damage state (e.g., slight, moderate, and extensive), and a damage-loss function transforms damage severity into corresponding seismic loss. It is noted that uncertainty associated with every step of the computation is taken into account and is propagated. The insurance-related risk can be evaluated by applying an insurance policy function to the estimated seismic loss (either at policy level or at aggregate level). The estimated loss results can be sorted in an ascending order to develop an EP curve for the portfolio of interest. An illustrative EP curve for an insurance portfolio, which plots estimated insurance loss as a function of annual exceedance probability, is shown in Fig. 5. The EP curve is often used for insurance portfolio decision-making. Note that there are many variants of the abovementioned method, such as a multiple-event/event-loss-table method (e.g., Dong and Grossi 2005).

Insurance and Reinsurance Models for Earthquake,

Fig. 5 Exceedance probability curve and risk metrics

Insurance and Reinsurance Models for Earthquake, Table 2 Summary of risk metrics

Risk metrics	Equation	Relationship with the EP curve
Annual expected loss: AEL	$AEI = E[L]$ where $E[\bullet]$ is the expectation	Area under the EP curve
Value at risk: Var_α	$Var_\alpha = \inf\{l : P(L > l) \leq 1 - \alpha\}$ where $\inf\{\bullet\}$ is the infimum and $P(L > l)$ is the probability of loss L exceeding a certain loss level l	Fractile value at a selected cumulative probability level α
Conditional value at risk: $CVaR_\alpha$	$CVaR_\alpha = \frac{1}{1-\alpha} \int_\alpha^1 Var_u du$	Area under the EP curve below a selected cumulative probability level α , normalized by the exceedance probability $1-\alpha$
Ruin probability	$P_{\text{ruin}} = P(L > R_{\text{insurer}})$ where R_{insurer} is the insurer's risk reserve	Probability when insurer's reserve fund is depleted

Note: α represents the cumulative probability; in other words, $1-\alpha$ represents the exceedance probability

To facilitate the risk-based decision-making and risk communication among different stakeholders, risk metrics can be derived from the calculated EP curve. Risk metrics that are widely used include: annual expected loss (AEL), probable maximum loss (PML), value at risk (VaR), conditional value at risk (CVaR), and ruin probability. The equations to compute these measures (except for PML) are summarized in Table 2 (see also Fig. 5 for graphical representation of the metrics). The AEL is a useful metric for ordinary risks; however, it is not suitable for catastrophic risks as it fails to capture the extent of devastating consequences due to rare events. The VaR is the fractile value on an EP curve corresponding to a selected probability level, while the CVaR, which is also referred to as expected shortfall in finance, accounts for rare events in terms of their severity and frequency by taking the conditional expectation of the EP curve. One of the crucial factors is “which probability level” to be focused upon in evaluating VaR and CVaR (also applicable to PML). The ruin probability represents the chance of insurer's insolvency (i.e., all reserve funds are depleted) and is often used for insurance regulatory purposes (e.g., an insurer needs to retain a sufficient reserve fund such that annual probability of insolvency is less than 0.005). The PML is one of the most popular metrics in financial risk management, and there are several definitions. Conventionally, it was defined as the fractile of the loss corresponding to the return period of 475 years (i.e., essentially same as VaR).

However, in different industries and countries, variants of the PML had been adopted for use. For example, in Japan, the PML is defined as the (conditional) 0.9-fractile value for a scenario that corresponds to a selected probability level (typically, return period of 475 years is considered, but this can be varied). Currently, specific nomenclatures are in use: scenario expected loss (SEL) corresponds to the original PML definition (i.e., VaR), and scenario upper loss (SUL) corresponds to the PML definition in Japan.

The CAT modeling is useful for quantifying insurers'/reinsurers' earthquake risk exposure under different situations and for deciding risk management strategies. For instance, impact of the policy function parameters (i.e., coinsurance, deductible, and limit) on insurer's earthquake risk exposure is illustrated in Fig. 6. The insurance portfolio is based on 4,000 wooden houses in Vancouver, Canada, and the EP curve is obtained from the stochastic earthquake catalog method (Goda and Yoshikawa 2012). Figure 6 shows that a high deductible and low coinsurance factor reduces earthquake risk exposure significantly at wide probability levels, whereas a low limit curtails the maximum earthquake risk exposure effectively. The limit tapers heavy right tail of the loss distribution and affects the deficit at ruin, which is one of the key decision variables in earthquake insurance management. Importantly, from insurer's viewpoint, flexibility to select a suitable policy arrangement is beneficial to enhance the performance of earthquake portfolio

Insurance and Reinsurance Models for Earthquake, Fig. 6 Effects of policy function parameters on exceedance probability curve: (a) coinsurance, (b) deductible, and (c) limit

management and to offer affordable insurance rates to the policyholders. However, such flexibility is not usually possible due to regulatory rules; in such cases, ART tools can be used.

Actuarial and Financial Insurance Model

Insurance models in actuarial sciences and financial engineering have a long history of development and wide applications in assessing underwriting risks. Popular approaches for characterizing catastrophic risk processes include a compound Poisson process (e.g., Rolski

et al. 1999) and an extreme value theory (e.g., McNeil et al. 2005). The risk process can be formulated in form of stochastic differential equations. Although analytical solutions for insurer's ruin probability are available for simple cases (e.g., compound Poisson process with exponential insurance loss), for realistic and complex problems, such solutions are not available and numerical simulations of the risk process are often required. On the other hand, statistical modeling of dependent risk processes is useful for assessing insurer's risk exposure due to

extreme events. In particular, accurate modeling of exposure dependence among different portfolios and lines of business is important in evaluating the entire risk process. This leads to advancement of dynamic financial analysis (Kaufmann et al. 2001), which integrates large-scale stochastic simulations of all related insurance and reinsurance processes (including fluctuating interest rates and catastrophic as well as non-catastrophic risks). The key challenge for both approaches is how to incorporate spatiotemporally correlated insurance claims in the risk process. In this section, two insurance models based on a compound Poisson (including diffusion-jump) process and based on extreme value theory are briefly mentioned (note: rigorous mathematical formulations are beyond the scope of this entry).

Compound Poisson and Diffusion-Jump Processes: The fluctuation of an insurer's wealth $W(t)$ subjected to both catastrophe and non-catastrophe risks, $W_{\text{noncat}}(t)$ and $W_{\text{cat}}(t)$, can be expressed as

$$W(t) = W_{\text{noncat}}(t) + W_{\text{cat}}(t) \quad (3)$$

In the context of earthquake insurance, $W_{\text{noncat}}(t)$ is related to ordinary risks (e.g., diversifiable liability insurance underwriting) and can be represented by a stochastic growth model, such as Brownian process and geometric Brownian process. The Brownian process assumes that changes of the wealth state over a short period are independent and identically distributed (*i.i.d.*) as normal variate, whereas the geometric Brownian process considers that the logarithmic ratio of two wealth states separated by short time lag is an *i.i.d.* normal variate. For instance, by adopting the geometric Brownian process, $W_{\text{noncat}}(t)$, representing incurred loss process, payout process, expense process, and investment process, can be described as

$$W_{\text{noncat}}(t) = W_0 \exp[(\alpha - 0.5\beta^2)t + \beta Z(t)] \quad (4)$$

where W_0 is the initial asset; α and β are the instantaneous growth rate and infinitesimal

standard deviation (or volatility) of the insurer's wealth related to non-catastrophic risks, respectively; and $Z(t)$ is a standard Brownian motion due to perturbation of non-catastrophic risk processes. In practical applications, the drift and volatility parameters α and β can be estimated from relevant insurance data (see Goda and Yoshikawa 2012). The stochastic process shown in Eq. 4 can be evaluated using Monte Carlo simulation, and thus many realizations can be generated to assess the temporal evolution of the insurer's asset.

The catastrophic jump component of the risk process $W_{\text{cat}}(t)$ occurs infrequently, but when it occurs, a drop of the insurer's net worth can be extremely large. Potentially, such a downward jump causes a negative net worth, forcing an insurer to become insolvent (i.e., $W(t) < 0$). This can be mathematically represented by a compound Poisson jump process:

$$W_{\text{cat}}(t) = - \sum_{i=1}^{N(t)} L_i \quad (5)$$

where jumps (i.e., damaging earthquakes) arrive randomly according to a Poisson counting process $N(t)$ and the random size of the jumps is characterized by a probabilistic loss model. Cossette et al. (2003) presented three different formulations of the catastrophic loss model L in Eq. 5 by considering independent, fully correlated, and partially correlated cases. The degree of loss correlation from multiple policies was defined as a function of seismic intensity, which is realistic. In addition, they derived the risk-ordering relationships of the different types of portfolios with respect to loss correlation for several risk metrics, including VaR and CVaR. It is noteworthy that the jump process shown in Eq. 5 can be substituted by an earthquake CAT model, which is more rigorous and accurate than a compound Poisson process.

The abovementioned stochastic representation of insurer's wealth process is illustrated in Fig. 7. Due to the earthquake's strike, insurer's wealth state is affected by earthquake insurance claims; this may force the insurer to become insolvent or

Insurance and Reinsurance Models for Earthquake, Fig. 7 Stochastic wealth process with and without insurance

be in debt. Furthermore, financial constraints caused by the earthquake risk may result in slow recovery from the shock after the earthquake. The figure also includes a hypothetical case where the insurer has arranged reinsurance coverage for the loss; in this case, the wealth state is dropped but not to the level of insolvency, and the post-disaster recovery rate may be more rapid than the situation without reinsurance (e.g., liquidity constraints are avoided). Stochastic simulations of underwriters' risk processes are useful for investigating the effects of insurance policies and reinsurance on the portfolio and for developing effective risk management strategies.

Extreme Value Theory and Copula-Based Dependence Modeling: The statistical modeling of extreme earthquake events is one of the active research areas. Useful statistical models for capturing the key features of a highly correlated loss generation process are the extreme value distributions (McNeil et al. 2005). In particular, the peak-over-threshold (POT) model is suitable as it utilizes all data exceeding a high threshold value more efficiently than the block maxima model and is more applicable to insurance loss processes (focusing on large, rare loss events). The limiting distribution of the POT data Y that exceeds a sufficiently high threshold μ converges to the generalized Pareto (GP) distribution:

$$P(X \leq x | X > \mu) = \begin{cases} 1 - (1 + \xi[x - \mu]/\beta)^{-1/\xi} & \xi \neq 0 \\ 1 - \exp(-[x - \mu]/\beta) & \xi = 0 \end{cases} \quad (6)$$

where ξ is the shape parameter and determines the upper tail behavior of the data and β is the scale parameter. Usually, a suitable value of μ can be determined based on mean excess and shape parameter plots (McNeil et al. 2005), and given data μ , it is straightforward to estimate the parameters of the GP model based on the maximum likelihood method.

In insurance portfolio management, multivariate modeling of insurance data may be required (e.g., portfolio aggregation; if locations of two portfolios are geographically close, they are subjected to similar but not identical earthquake risks). In such a case, a dependence structure of the data needs to be characterized. To deal with insurance data having heavy right-tail and

Insurance and Reinsurance Models for Earthquake, Fig. 8 Statistical aggregation of two insurance portfolios

nonlinear dependence, a copula technique can be used (McNeil et al. 2005); the major advantage of the copula is that the dependence modeling can be carried out in isolation from the marginal distribution modeling. The copula model fitting can be performed by finding a parametric copula function that fits best to empirical copula data (transformed data such that their marginal distributions are uniformly distributed) using the maximum likelihood method. There is a wide class of copula functions (e.g., elliptical copula and Archimedean copula).

To illustrate an application of the statistical modeling approach to earthquake insurance loss, results for aggregation of two insurance portfolios at closely located locations are presented in Fig. 8 (Goda and Ren 2013). Two portfolios, each consisting of 400 houses in a 1 km by 1 km area, are considered; the two portfolios are separated by 1 km, and thus high correlation is anticipated, particularly in the upper tail (i.e., large loss in one portfolio is likely to be accompanied by large loss in the other portfolio). The insurance loss samples are generated from the stochastic earthquake catalog approach. To model the joint seismic loss distribution of the two portfolios, GP models are fitted to the marginal distributions of the two portfolios, and a suitable copula function, which is found to

be the heavy right-tail copula, is obtained. Then, using the constructed joint probability distribution, insurance loss samples are generated and plotted in Fig. 8. Comparison of the two EP curves indicates that, except for the intermediate loss range, agreement of the combined insurance loss data is good; see Goda and Ren (2013) for more comprehensive results. It is emphasized that the simulation from the statistical model is very quick, in comparison with the CAT model. Therefore, once the accuracy of the statistical method is verified, the proposed method can serve as a viable alternative to conduct various sensitivity analyses related to earthquake insurance portfolios (i.e., comparison of EP curves and risk metrics under different policy functions and reinsurance arrangements).

Economic Insurance Model

In economics, decision problems of providing insurance coverage have been studied extensively from two perspectives: (i) homeowner's demand (Mossin 1968; Schlesinger 2000) and (ii) insurer's supply (Kleindorfer et al. 2005). Other relevant problems include economic valuation and decision-making related to risk mitigation actions, such as self-insurance, self-protection, and market insurance (Ehrlich and Becker 1972). The essential tools that have been

used in such analyses are based on the expected utility framework (note: recent studies adopt descriptive decision theories to analyze the abovementioned problems). Typically, a homeowner is assumed to be a risk-averse decision maker, having a concave utility function, whereas an insurer is considered to be a risk-neutral decision maker, having a linear utility function. To simplify situations, two contingent states only, i.e., no earthquake damage and full earthquake damage, are often considered. The conclusions and theorems derived from these idealized analyses provide useful insight on rational behavior of homeowners and insurers toward insurance decision-making under uncertainty. It is important to recognize that these theoretical predictions are obtained based on many (critical) assumptions about risk attitudes of decision makers and market conditions, which may be invalid in reality and inapplicable to catastrophic earthquake risks. In the following, brief summaries of insurance decision-making models for the two cases are given.

Insurance Demand Decisions by Homeowners: A simple form of homeowner's demand problem for earthquake coverage is the following: (i) a homeowner has a utility function U (typically, concave function); (ii) earthquake damage can occur with probability of π (note: there are two contingent states only), and should this happen, he/she will lose a property valued at L ; (iii) the owner has an additional asset valued at A ; (iv) the owner pays a premium P_I . Under these assumptions, the expected utility without insurance can be expressed as $\pi U(A) + (1 - \pi)U(A + L)$, while that with (full) insurance is $U(A + L - P_I)$. The maximum insurance premium that the owner is willing to pay can be obtained by setting the derivative of the objective function:

$$O = \pi U(A) + (1 - \pi)U(A + L) - U(A + L - P_I) \quad (7)$$

with respect to an insurance parameter equal to zero and by finding a solution of the equation. A similar setup can be used for more elaborated cases to analyze the effects due to asset, policy function structure (e.g., coinsurance/deductible/

limit), risk attitude (utility function and degree of risk aversion), and risk premium (Schlesinger 2000). Recently, Asprone et al. (2013) have applied an extended version of the insurance demand model by considering multiple damage/loss levels to determine insurance premiums of building stocks in Italy.

Insurance Supply Decisions by Insurers: The supply of earthquake coverage is influenced by various factors. Insurer's main concerns in offering earthquake coverage are profitability and fear of insolvency. This insurer's decision problem can be formulated as the profit maximization subjected to survival and stability constraints. The survival criterion requires that ruin probability should be less than a threshold value (which may be given by a regulatory body exogenously), whereas the stability criterion requires that probability of operational costs (i.e., sum of claim payments and expenses) exceeding a certain threshold value should be sufficiently small. Each of these criteria produces the maximum number of policies that can be offered for a given policy-premium structure. If the maximum number of policies based on the two constraints does not exceed the minimum number of policies required to initiate such coverage, the insurer will not offer earthquake insurance. Although the above economic analysis highlights a rational basis for insurer's supply decisions, insurers tend to adopt heuristic criteria based on simpler risk metrics, such as PML and VaR.

Integrated Earthquake Risk Management

Recent catastrophes in Chile and Japan have revealed insufficiency of conventional financial risk management tools and systems, such as self-insurance, public support, and earthquake insurance. Muir-Wood (2011) suggested that for Chile, micro-insurance, targeted for low-income homeowners and small commercial enterprises, should be introduced and a new risk-pooling system should be set up to cover earthquake risks for government-owned buildings. The former issue is compounded by anticipation of ex post

subsidies from governments by Chilean people (charity hazard); however, it has been demonstrated that DRR measures are far more cost-effective than no DRR situation (Kleindorfer et al. 2005; Michel-Kerjan et al. 2013). In Japan, relatively low penetration rates of earthquake insurance (about 27 % in 2013) should be increased to achieve a nationwide risk-sharing mechanism with stable incomes; this situation was contrasted by the earthquake insurance coverage in New Zealand after the 2010–2011 Christchurch sequences. It is also important to implement risk-based insurance premiums for different structural types and seismic regions (e.g., California, Japan, and Turkey) and introduce financial incentive schemes to promote DRR investments (e.g., Japan). Such proactive earthquake risk management is the key to achieve sustainable and resilient communities against earthquake disasters.

In the envisaged risk management framework, the role of insurers, reinsurers, and governments is important. Major challenges in the current earthquake risk finance systems are related to securing sufficient funds to cover potential earthquake loss. The development of catastrophe securitization markets enables earthquake risk underwriters to have access to greater financial resources (Grace et al. 2003; Lalonde 2005; Cummins 2008). Broadly, there are three types of catastrophe insurance securities: indemnity-based securitization, index-based securitization, and parametric securitization. The indemnity-based securities are essentially the same as reinsurance contracts (but offered in form of securities), for which the loss repayment is determined based on actual security-issuer's (sponsor's) loss. Thus it suffers from the same issues as reinsurance, such as moral hazard and asymmetrical information. The index-based securities adopt actual industry-wide loss due to a damaging earthquake, rather than actual sponsor's loss. Advantages of this type of securitization include: reduced effects of moral hazard and transparency of loss information (note: individual companies are generally reluctant to reveal detailed information on their risk exposures). Difficulties arise in pricing such securities because industry loss and

company's loss are not fully correlated. In other words, the index-based securities are subjected to basis risk.

Recently, parametric securities, such as CAT bonds, have become popular. A typical setup for the CAT bonds is as follows. A single-purpose reinsurer collects funds (principal) from investors in the markets and issues CAT bonds. In cases pre-agreed/specified trigger conditions are met, the principal is paid to the sponsor; otherwise, the principal together with return higher than typical securities is paid back to the investors when the bonds mature. Triggering of the bond payments is determined based on the intensity of physical earthquake parameters, such as a combination of earthquake magnitude and location and instrumentally obtained seismic intensity measures. As estimates of the earthquake intensity parameters are promptly available from reliable third bodies (e.g., US Geological Survey and Japan Meteorological Agency) immediately after an event, bond payments become available soon after the earthquake. This is not the case for the other two types of securities; assessment and settlement of earthquake loss take a long time. Generally, in comparison with reinsurance, the CAT bonds have three main advantages: (i) relatively large total value of bonds can be issued with low default risk, because the capital markets have significantly greater risk-bearing capacity compared with reinsurance industry, (ii) principal is accessible immediately after a disaster (high liquidity), and (3) moral hazard is minimized. A main disadvantage of the CAT bonds is basis risk, i.e., discrepancy between actual loss incurred by the sponsor and payment received by the sponsor (similar to index-based securities). It consists of model risk and trigger risk. Model risk arises because the structure of the CAT bonds is often designed based on numerical CAT models, whereas trigger risk is related to inaccuracy of an adopted trigger mechanism in terms of physical seismic parameters. The basis risk can be reduced by adopting an improved version of the CAT model and by implementing an advanced trigger mechanism that uses more local seismic information (e.g., instrumental measures from nearby recording stations, rather

Insurance and Reinsurance Models for Earthquake, Fig. 9 Insurance portfolio management using seismic upgrading, reinsurance, and CAT bonds

than earthquake event characteristics; Goda (2014). In this regard, progress in the CAT modeling, contributed by all involved disciplines, has direct impact on the reliability of the CAT bonds.

Lastly, to illustrate a practical application of CAT bonds in insurance portfolio management, EP curves for four cases are presented in Fig. 9: (i) no risk mitigation/transfer; (ii) CAT bonds with trigger attachment and exhaustion points of \$20 and \$40 million, respectively; (iii) reinsurance with attachment and exhaustion points of \$20 and \$60 million and pro rata ratio of 0.2; and (iv) seismic upgrading (implementation of seismic provisions). The base portfolio is comprised of 1,000 wooden houses designed without seismic provisions, and the costs to implement the risk mitigation/transfer measures are included in the EP curves. The details of the analysis setup can be found in Goda (2014). All three risk mitigation/transfer options are effective in reducing insurer's earthquake exposure. The EP curve for the reinsurance contract has clear kinks, which correspond to the policy attachment and exhaustion points. The three options transform the original EP curve differently; reinsurance has clear influence on the specific loss layer between the attachment and exhaustion points, while seismic upgrading essentially shifts the EP curve

downward (i.e., chance of experiencing seismic loss is decreased because of enhanced seismic resistance). The influence of the CAT bonds is more widely distributed (note: the EP curve for the CAT-bond case includes the triggering errors). Importantly, the numerical CAT modeling results combined with quantitative risk metrics for different risk management strategies provide valuable insight on the earthquake risk exposure. This facilitates risk-based decision-making and cost-benefit analysis.

Summary

This entry reviewed a broad range of topics related to earthquake insurance and reinsurance. An emphasis was given to the role of insurance and reinsurance in mitigating financial consequences of catastrophic earthquakes as integrated part of disaster risk reduction. Basic terminologies and current insurance-reinsurance systems were introduced. In particular, challenges related to low-probability high-consequence risk characteristics were discussed. Various insurance and reinsurance models that have been developed and applied in different academic fields were described. The fast-evolving earthquake

catastrophe modeling techniques were summarized in the context of earthquake insurance portfolio management (including quantitative risk metrics). Subsequently, actuarial and financial insurance models, both statistical and computational, were presented. The homeowner's and insurer's decision models were then summarized. A sequential application of different insurance models (e.g., catastrophe modeling combined with dynamic financial analysis) is the state of the art in practice, requiring broad knowledge and understanding of available techniques. Finally, utilization of emerging alternative risk transfer tools, such as catastrophe bonds, was discussed to promote an integrated earthquake risk management framework.

losses can be prevented by implementing sound disaster mitigation plans; retrofitting the infrastructures, implementing good crisis management and recovery plans, etc. (NEES report 2004). This requires reliable predictions of damages due to anticipating earthquake scenarios. The conventional predictions are based on empirical relations which are obtained by statistical analysis of past earthquake disasters. These empirical predictions are less reliable since the conditions during the recorded major earthquakes, which are rare and have return periods of half a century or more, are significantly different from the conditions at the time of next major earthquake. During the long periods between major earthquakes, built environment and social and economic systems undergo significant changes. As an example, social and economic systems increasingly rely on lifeline networks, like electricity, communication, water, gas, sewer, transportation, etc., making it possible for any malfunction or damage to propagate way beyond what have been experienced during the past earthquake disasters. Even some of these vital lifelines may not have existed at the time of many of the past major events. Therefore, the next major earthquakes can easily outpace the earthquake mitigation efforts based on these empirical predictions.

Predictions, which take the current state of an urban system into account, enable to implement disaster mitigation and recovery plans, which must be significantly successful compared to those made solely based on the past earthquake disaster information. More reliable and detailed prediction of damages to buildings, lifelines, and other structures can be made if the enhanced materials and updated design codes used for the constructions and the current state are taken into account. Such predictions based on up-to-date information can restrain the propagation of damages and malfunctions in lifeline networks, which are becoming increasingly interdependent. With detailed, comprehensive, and reliable predictions, decision makers can prepare a sound recovery plan which minimizes the post disaster economic damages and restores the social system in a shorter time. Thus, what is necessary is

Integrated Earthquake Simulation

End-to-end earthquake simulations; Large-scale earthquake simulations

Introduction

A major earthquake in a commercial metropolis can inflict catastrophic disasters, crippling economy, causing loss of lives, and damaging infrastructure and properties. Even though the earthquake itself cannot be predicted, it is a possibility that the associated catastrophic

detailed and comprehensive disaster prediction which considers the current state of built environment, social system, economy, etc. (Hori 2011).

Integrated earthquake simulation is a new paradigm which enables detailed and comprehensive analysis earthquake disasters in large urban system, taking the current state of built environment, social systems, etc. into account. The rapid progress of earth sciences, earthquake engineering, disaster mitigation sciences, and social sciences has produced well-established numerical tools for simulating many phases involved in an earthquake scenario. These numerical tools can be utilized to seamlessly simulate all the phases involved in an earthquake disaster, in high spatial and temporal resolutions. Opposing to the conventional disaster predictions, the use of such numerical simulations for disaster predictions has two main advantages: current state of built environment and socioeconomic systems can be taken into account; a large ensemble of plausible future earthquake scenarios can be taken into account. These two advantages address the major weaknesses of the conventional predictions, making the predictions based on integrated earthquake simulations more reliable.

Many of the numerical methods and tools necessary for building an integrated earthquake simulator already exist. Hence, the major task involved in developing an integrated earthquake simulator is to build a system which seamlessly integrates the necessary numerical tools for end-to-end earthquake simulations, for suitable computer hardware. There are well-developed numerical tools for earthquake hazard and disaster simulations, while the methodologies and numerical tools for simulating human responses, like evacuation, recovery, etc., are being developed. Despite the availability of some of the required numerical tools, it is not a trivial task to build a seamlessly integrated system. Several problems have to be addressed: lack of consistency between the inputs and outputs of some numerical tools, lack of numerical tools for simulating some phases, automation of analysis model constructions for large metropolis, efficient utilization of high-performance computing resources, etc.

The need for detailed, comprehensive, and reliable earthquake disaster predictions and the wide availability of high-performance computing resources have initiated several research activities on integrated earthquake simulation systems (Hori and Ichimura 2008; Hori 2011; Taborda and Bielak 2011; Muto et al. 2008). Further, the need of an integrated system for more reliable earthquake predictions has been emphasized by the Committee to Develop a Long-Term Research Agenda for the Network for Earthquake Engineering Simulation of the USA (NEES report 2004). Most of the existing integrated systems consider only the integration of earthquake hazard and seismic response of man-made structures. Taborda and Bielak (2011) have demonstrated the application of an integrated system to simulate wave propagation in large basins, amplification in surface layers, and seismic response of a small number of buildings. Muto et al. (2008) have presented a system for simulating rupture process to building damage and estimating repair costs, with small-scale seismic response analysis simulations. Hori et al. (Hori and Ichimura 2008; Hori 2011; Sobhaninejad et al. 2011) have developed a system called integrated earthquake simulator (IES) with the aim of seamlessly simulating all the involved phenomena from earthquake hazard to human responses, in large scale. They have proposed a macro-micro analysis method which not only efficiently simulate wave propagation and amplification in large domains but also treats the uncertainties due to lack of underground structure data. Also, the IES consists of an evacuation simulation module which can simulate evacuation in smaller-scale domains (Hori 2011).

The objective of this entry is to present an overview of integrated earthquake simulations. Being the most complete available integrated earthquake simulation system, most of the contents of this entry are prepared based on Hori et al.'s integrated earthquake simulator (Hori and Ichimura 2008; Hori 2011; Sobhaninejad et al. 2011). In the next section, an overview of integrated earthquake simulations is presented. The remaining sections present some details of earthquake hazard and disaster simulations;

neither tsunami nor human responses are included since these are not included in the available integrated systems. A short description of the numerical methods used for earthquake hazard and disaster simulations and automated analysis model construction based on GIS data are presented in these two sections. The last section presents a summary of the contents and a list of challenging problems which have to be addressed in the future.

Integrated System for End-to-End Earthquake Simulations

An integrated earthquake simulation system consists of a set of numerical tools, which are seamlessly integrated, for simulating the three main phases of an earthquake; earthquake and tsunami hazard, earthquake and tsunami disaster, and human actions against the earthquake disaster (see Fig. 1). Different numerical simulations that are used for simulating each of these three phases are summarized below.

1. Hazard simulations

- (a) Earthquake hazard simulation: For a given fault mechanism, an earthquake wave is synthesized and propagation through the

crust is computed. Considering the 3D topographical effects and nonlinear properties of surface soil layers, wave amplification (i.e., strong ground motion) at the target area is computed. The output of the strong ground motion calculation should be consistent with the spatial and temporal resolutions required for seismic response analysis of man-made structures.

- (b) Tsunami hazard simulation: For a given fault mechanism, ocean bottom deformation and tsunami wave propagation are simulated.

2. Disaster simulations

- (a) Earthquake disaster simulation: Seismic responses of all the structures, both on the surface and underground, are computed using the strong ground motion data obtained in the hazard simulations. Depending on the type of each structure, a suitable numerical analysis method has to be used. This simulation should produce the necessary outputs, like the damage state of a building, which are required for human action simulations.
- (b) Tsunami disaster simulation: Simulation of tsunami flow in the target area considering the fluid structure interaction and damages to man-made structures due to

Integrated Earthquake Simulation, Fig. 1 Overview of integrated earthquake simulations

tsunami wave and the debris it carries. Though it is a challenging problem, simulation of damages to man-made structures is essential for the recovery process simulation.

3. Human actions against disasters

- (a) Evacuation: Generally, this involves the simulation of evacuation of buildings and moving to a safe location. In regions prone to tsunami disasters, moving to a safe high ground has to be simulated considering the human behaviors in time-critical events and the time history of inundation. The environment model of evacuation simulation should be modified, according to the results of the earthquake disaster simulation, so that unexpected delays caused by narrowing and blockages of roads are incorporated.
- (b) Crisis management: Simulation of possible emergency situations like fire, flooding, etc.
- (c) Recovery: Simulation of allocation and consumption of resource, like manpower, energy, materials, etc., to recover from the disaster, and estimate the resulting social and economic benefits.

In short, given the input data of a target area and a fault mechanism, an integrated system calculates the damages to the built environment and both the short-term and long-term human actions against the disaster. For the seismic hazard and disaster simulations, the required inputs are the data of underground structures, man-made structures, and a possible fault mechanism. The output of the disaster simulations should produce the necessary data for the simulation of human actions. In addition to the data from the disaster simulation, the human-response simulations require more data like the distribution of people at the time of the disaster and their properties, cost of repairing various damaged components, availability of various resources and manpower, etc. It would be a useful tool for decision makers, if the recovery simulation includes capabilities to find optimal way to allocate resources for a given damage state.

Applications

The main application of an integrated earthquake simulation system is to make detailed and comprehensive earthquake disaster predictions using the current state of built environment, social systems, and economy. This involves many uncertainties like the fault mechanism and the location of the next earthquake, lack of geological and underground structure data, etc. Unless these uncertainties are taken into consideration, the predictions of the integrated system are useless; what the decision makers need is predictions of high reliability so that they can use the predictions to implement disaster mitigation and recovery plans. In order to make reliable predictions, accounting the uncertainties of input data, some kind of stochastic approach like Monte Carlo simulation is necessary; Monte Carlo simulation is the widely used method for simulating this kind of phenomena involving significant uncertainties in input data. The detailed, comprehensive, and reliable predictions using an integrated earthquake simulator will ultimately make it possible to prevent catastrophic losses even though the anticipating earthquakes cannot be predicted.

In addition to the abovementioned main application, an integrated earthquake simulation system can be used for many other applications, some of which are listed below:

- As a tool for land-use planners to decide the required regulations or usages compatible with expected level of risk, when developing regions prone to seismic hazards. An integrated system can be used to assess the hazard level and find the construction standards and response measures which are necessary to prevent disasters in regions with seismic hazards. Then the public and policy makers can be informed of the earthquake risk, necessary planning and construction, and necessary response measures to reduce risks (NEES report 2004).
- For performance-based structural designs.
- Augmented reality and the results from a validated integrated system can be used to convince the political leaders and the public

Integrated Earthquake Simulation, Fig. 2 A

basic structure of an integrated earthquake simulator. Common modeling data (CMD) is the internal data format used by Hori et al.

that new disaster mitigation strategies are effective and economically viable risks (NEES report 2004).

- As a training tool for emergency and relief supply staffs, etc.

Not all the abovementioned numerical tools are included in present integrated earthquake simulators. Most of the existing integrated simulators include only the numerical tools for earthquake hazard and earthquake disaster simulations. The remaining sections provide detailed information of these numerical tools available in present-day integrated earthquake simulators. Though several numerical methods for tsunami hazard simulations are available (Goto et al. 1997; Mader 2004), there is a lack of numerical tools for simulating the tsunami disaster. The existing numerical tools only estimate the inundation and run-up height, and damages to man-made structures in large areas are not considered. Also, there are no well-established techniques for simulating other human responses, except the evacuation simulations. Multi-agent systems have been developed to simulate evacuation triggered by earthquakes or tsunamis. However, these tools are not sufficiently mature to simulate large urban area evacuations, which is the target domain of an integrated system.

Therefore, the remaining sections only focus on the earthquake hazard and disaster simulations.

Development of an Integrated System

Figure 2 shows a basic structure for an integrated earthquake simulator, proposed by Sobhaninejad et al. (see also Hori 2011). The kernel is the control center which controls the whole system. It controls inputs and outputs of the system and calls the individual simulation codes in proper order, providing the necessary input data and retrieving output data which are required for subsequent analysis codes. Each item shown in the simulation layer of Fig. 2 consists of a microkernel which controls the flow of each simulated phase. As an example, the seismic response analysis's microkernel controls how a large number of structures in a city is being executed, using suitable numerical tools to simulate different types of structures made of concrete, steel, wood, etc. Also, the microkernel distributes these structures among a large number of CPUs in high-performance computing (HPC) hardware such that all the CPUs have equal work loads. The use of HPC is essential to simulate millions of buildings in large metropolises.

Geographic information system (GIS) data is one of the prominent input data for an integrated earthquake simulator (Hori 2011). GISs are

widely used by many governmental and private organizations to store data. As an example, in Japan, GISs of ground elevation, borehole data, shapes of buildings, etc. are available. These data can be utilized to generate analysis model of metropolis. However, these GISs do not contain all the essential information for generating analysis models. As an example, GIS does not contain essential data for seismic response analysis like structural skeleton of buildings, material properties, etc. Although the necessary information is unavailable in current systems, the quantity and quality of GIS data are continuously improved. The next two sections present how to construct analysis models for earthquake hazard and disaster simulations based on GISs containing borehole data and configurations of buildings.

As for the development language, an object-oriented language, like C++ or python, is suitable since object-oriented features are convenient in large and complex system development: the ease of large project management with multiple developers, the ease of long-term software maintenance, ability to develop intuitive user interfaces, availability of generic programming, etc. Further, the ability to call libraries written from any of the standard languages and availability of several inter-process communication methods make it easier to integrate numerical tools developed with any language.

Being a system consisting of a number of different numerical tools, an integrated system requires a suitable internal data format to efficiently manage the flow of data among the numerical tools (Hori 2011; Sobhaninejad et al. 2011). The numerical tools for simulating various phases are usually provided by different research groups and have different data formats. Usage of multiple data formats has several problems: requires many data conversions, readability and maintainability of the source codes are poor, etc. The standard method of solving this problem is maintaining one internal data format with which the kernels interact with each other and the various numerical tools. Microkernels are responsible for translating the internal data format when interacting with the numerical tools. It would be an advantage if the basic elements of

the selected internal data format are readily exchangeable among CPUs with Message Passing Interface (MPI), which is the widely used standard library in parallel computing.

Some of the Difficulties Involved in Integrated System Development

Though it appears that integrating existing numerical tool to build an integrated earthquake simulator is simple, it involves several difficulties and challenges like:

- Lack of necessary numerical tools
- Incompatibility of inputs and outputs of some numerical tools
- Need of automated model construction
- Optimal utilization of high-performance computing resources
- Verification and validation of the integrated system

As mentioned above, there is a lack of well-developed numerical tools or methods to simulate certain phases like tsunami disaster and human responses. The incompatibility of inputs and outputs of different numerical tools is also a problem in integrating numerical tools. The outputs of most of the necessary numerical tools, which are developed in different disciplines, may not have consistent spatial and temporal resolutions required for subsequent analysis. To address this problem, close collaborations with the developers of relevant simulation tools are necessary. Being the analysis domains very large, automation of analysis model construction is essential, which is a challenging task; automated construction of suitable analysis model for each of millions of structures in a metropolis, based on available CAD or GIS data, is not trivial.

Enhancing an integrated system to optimally use high-performance computing (HPC) resources is also a major challenge. Obviously, optimal utilization of cutting-edge supercomputing resources is necessary to simulate a large metropolis. While there are HPC-enhanced numerical tools for hazard simulations, HPC-enhanced codes disaster simulation and human response have to be developed.

Further, building a seamlessly integrated system (i.e., a system which will simulate end-to-end process in a single execution) is challenging due to two main problems. The first problem is that even though each numerical tool is enhanced to optimally use supercomputing resources, it does not guarantee that a seamlessly integrated system can optimally utilize the supercomputing hardware. The main reason is that different numerical tools involve different amount of computations; hence, there is a drastic difference in the maximum number of CPUs required for the optimal performance of each numerical tool. As an example, the earthquake hazard simulation requires several hundred thousand CPUs, while evacuation simulation requires only a few thousands of CPUs. This results in waste of CPU time. The second difficulty is that different numerical tools require different parallel computing approaches, which cannot coexist in single execution. As an example, hybrid of shared and distributed memory parallelism is the best for earthquake hazard simulations, while earthquake disaster and evacuation simulations require only the distributed parallelism. These two HPC challenges, involved in end-to-end simulations in a single execution, can be easily avoided by executing each numerical tool independently, which is the same as replacing the main kernel (see Fig. 2) with human control. However, this is not an acceptable solution since simulating a large number of earthquake scenarios is going to be laborious and error prone; as mentioned, Monte Carlo simulations are necessary for improving the reliability of the earthquake disaster simulations.

Hazard Simulation

There are two main hazards involved: earthquake and tsunami. Earthquake hazard involves simulations of wave propagation through crust and amplification in the surface layers. Tsunami hazard involves ocean bottom deformation and tsunami wave propagation from source to shore. There are well-developed numerical methods and large-scale simulation programs for both the methods. However, existing integrated

earthquake simulators only include the earthquake hazard, probably because tsunami hazards are rare though cause severe destruction. In this section, the available methods of earthquake hazard simulations and model generation from GIS data is presented.

Earthquake Hazard Simulations

Earthquake hazard simulation involves three main steps: simulation of fault rupture, simulation of seismic wave propagation through the earth's crust, and wave amplification when traveling through surface soil layers (see Fig. 1). Out of these three, fault mechanism is the least understood; rupture process has complex spatial and temporal characteristics. The other two steps are mechanical processes which are well understood, and there are several numerical methods to simulate wave propagation and amplification processes (Bielak et al. 2005; Hori and Ichimura 2008; Cui et al. 2009; Käser et al. 2008). The objective of earthquake hazard simulation is, for a given fault scenario, numerical simulation of wave propagation and amplification process, at sufficiently high spatial and temporal resolutions required for earthquake disaster simulations. Though the two mechanical processes are well understood, these involve two difficulties: required high-resolution simulations involve large-scale computing and lack of accurate geological and underground structure data. This subsection presents brief descriptions of available methods to overcome these problems.

While the dramatically improving supercomputing performance provides the necessary computation power, selection of proper numerical method is essential for the optimal usage of the computing resources. The two main numerical methods used for large-scale earthquake hazard simulations are finite difference method (FDM) and finite element method (FEM) (Moczo et al. 2007). Both methods have advantages and disadvantages (Bielak et al. 2005; Hori 2011; Taborda and Bielak 2011). FDM has been the most popular due to several reasons like the ease of implementation, the wide choice of explicit and implicit time stepping methods, sufficient robustness and accuracy, efficiency, etc.

However, due to the reliance of regular grid, the conventional FDM has several drawbacks, like the involvement of over-refined grid when modeling media with high contrast in material properties, need of smaller time steps, etc. The involvement of over-refined grid and smaller time steps dramatically increases the necessary computer resources and computing time. On the other hand, FEM does not involve these problems; longer time steps can be used and mesh can be adapted to model local features. These advantages become more dramatic with increasing contrast in shear wave velocity in the heterogeneous medium. The two major drawbacks of FEM are that a considerable effort is necessary to generate a refined mesh and storing global stiffness matrix requires considerable memory. Bielak et al. (2005) have proposed an octree-based FEM method to overcome both of these problems. The near-linear scalability up to 98,000 CPUs, when simulating $180 \times 135 \times 62 \text{ km}^3$ region, shows the potential of octree-based approach (Taborda and Bielak 2011). The macro-micro analysis method, proposed by Hori et al. (Hori and Ichimura 2008; Hori 2011), overcomes the abovementioned two problems using singular perturbation expansion and bounding medium theory. A brief description of macro-micro analysis is given below.

The uncertainty of geological and underground structures is a serious problem which hinders the high-resolution earthquake hazard simulations. The presently used in situ observations and other technologies for mapping the geological and underground structures are inefficient or not sufficiently accurate for generating high-resolution analysis models, which are required for accurate and high-resolution seismic hazard simulations. This hinders accurate disaster simulations; accurate damage predictions require seismic hazard simulations of high spatial and temporal resolutions. As explained below, the macro-micro analysis method uses bounding medium theory to overcome this uncertainty problem.

Macro-Micro Analysis Method

Macro-micro analysis method (Hori and Ichimura 2008; Hori 2011) is a stochastic method which

uses singular perturbation expansion and bounding medium theory to overcome the abovementioned two difficulties. In macro-micro analysis, a stochastic variational problem is posed to account the abovementioned uncertainties in geological and underground structures and material properties. In stochastic problems both the input variables with uncertainties and the output variables become random variables, which are defined both in physical space and probabilistic space. The inputs for the stochastic seismic hazard problem are the mean and variance of crust and ground structure configurations and mean and variance of uncertain material properties like density, Young's modulus, etc. Solving such stochastic problems is complex since the response of the system also becomes stochastic and not proportional to the variability of the input data. Micro-micro analysis method uses bounding medium theory to find optimistic and pessimistic estimates for the mean response of the stochastic model, without explicitly solving the stochastic problem using laborious or complex methods like Monte Carlo simulations or spectral method. The bounding medium theory determines two deterministic, but fictitious, models which provide optimistic and pessimistic estimates for the mean response.

The upper and lower bound models obtained with the bounding medium theory require large number of discretization according to the geometry and shear wave velocity of materials; hence, solving the resulting analysis models is computationally intensive. In order to efficiently solve this large-scale problem, which has wildly varying parameters, macro-micro analysis takes a multi-scale approach with singular perturbation expansion. Singular perturbation expansion is a mathematical technique which leads to multi-scale analysis. The resulting analyses in long and short scale are called macroanalysis and microanalysis. Macroanalysis considers the wave propagation in the entire domain in lower spatial resolution, while the microanalysis considers wave propagation in higher spatial resolution for each subdomain of interest. These two analyses are analogous to the wave propagation analysis in seismological scale and strong ground

Integrated Earthquake Simulation,

Fig. 3 Determination of consistent soil layers

motion analysis in surface layers of urban areas. For the sake of reducing memory consumption and efficient computer implementation, macro-micro analysis uses voxel finite element method (VFEM) (Koketsu et al. 2004; Hori 2011). In summary, macro-micro uses bounding medium theory and singular perturbation expansion to numerically efficiently simulate the seismic wave propagation and amplification in large domains, which is a problem involving parameters with uncertainties, in high spatial and temporal resolutions.

Construction of Ground Structure Model from Sparse Borehole Data

As mentioned, accurate models of surface layers are necessary for high-resolution prediction of wave amplification in mediums with low shear wave velocities. However, constructing an accurate model is difficult due to limited availability of borehole data, some of which are poor in quality. Often these borehole data are coming from scattered locations and are inconsistent; borehole data is considered inconsistent if the sequence and the number of distinct layers differ from site to site (see Fig. 3a). To make a model of underground structures, based on borehole data, Hori (Hori 2011) has proposed a method which involves two steps: find a reference sequence of soil layers consistent with the data of each borehole site and interpolate the obtained consistent layers to find soil layer information at any arbitrary point. The proposed scheme, which is used in geo-information geology, for estimating a consistent set of soil layers at each site involves the following four steps:

- (i) Choose one borehole and use its layers as the reference sequence.
- (ii) Pick another borehole and compare its layers with the reference sequence.
 - (a) If the sequences are matching, choose another.
 - (b) Else make a new reference sequence consistent with the both by combining those; some layers can be of zero thickness (see Fig. 3b).
- (iii) Repeat step ii to obtain a reference layer sequence consistent with all the boreholes.
- (iv) Finalize by eliminating any insignificant layers.

Once a sequence of soil layers consistent with each borehole is found, soil layer information at any location can be evaluated using a suitable interpolation scheme. Hori (2011) has proposed the following grid algorithm to interpolate and obtain soil layer information in a regular grid. In order to explain this grid algorithm, consider the problem of interpolating the elevation of a certain soil layer interface. Assume that consistent layer information at K number of borehole sites of the domain D are available. Let the spatial location boreholes and the elevation of the specific layer interface be $\{\mathbf{x}^k\}$ and $\{f^k\}$, where $k = 1, 2, \dots, K$. In order to interpolate $\{f^k\}$, a coarse fictitious grid is introduced. Let the grid points denote by $(\mathbf{x}^{n,m})$ and the fictitious elevation of the specific layer interface at corresponding grid locations be $f^{n,m}$. The elevation of the specific layer $f(\mathbf{x})$, at borehole location $\mathbf{x}$, can be expressed by using the data of the four neighboring fictitious grid points as follows (see Fig. 4):

Integrated Earthquake Simulation, Fig. 4 Fictitious grid and the weights used for the bilinear interpolation

$$f(x) = w_1(x)f^{n,m} + w_2(x)f^{n+1,m} + w_3(x)f^{n,m+1} + w_4(x)f^{n+1,m+1},$$

where $w_1, w_2, \dots, w_4$ are bilinear weight functions. The weights are the area fractions of the rectangles formed by x and the four grid points. As an example

$$w_1 = \frac{(x_1^{n+1} - x_1)(x_2^{m+1} - x_2)}{(x_1^{n+1} - x_1^n)(x_2^{m+1} - x_2^m)}.$$

Once a coarse grid is made, the above bilinear interpolation can be repeatedly applied to obtain soil layer data in a grid, which is sufficiently fine for setting material properties of VFEM model for the microanalysis. As explained above, macro-micro analysis uses bounding medium theory to handle the uncertainties in the layer configurations and material properties.

Disaster Simulation

Out of the two main disasters involved, seismic disaster has received more attention (Hori and Ichimura 2008; Muto et al. 2008; Hori 2011; Taborda et al. 2011). There are a number of numerical methods developed for seismic

response analysis of buildings and other structures. Some of these methods are validated and have been extensively used for the purposes like structural designs, performance evaluations, structural health monitoring, etc. On the contrary, there are no well-established numerical methods for simulating large urban area tsunami disasters, incorporating the damages to structures inflicted by tsunami wave and debris. Development, verification, and validation of numerical methods capable of simulating large area tsunami inundation, including the destruction it brings, are challenging research areas which are essential for integrated earthquake simulators. In this section, the available seismic response analysis methods for buildings and approximate analysis model construction based on GIS data are briefly explained.

Available Numerical Methods for Seismic Response Analysis of Buildings

There are several numerical methods for the seismic response analysis, ranging from simple single degree of freedom (SDOF) systems to sophisticated nonlinear FEM models which consider large deformation and damage. Some well-established numerical techniques used in structural response analysis are SDOF, multi-degree of freedom systems (MDOF), one-component model (OCM), discrete element method (DEM), fiber element model, and nonlinear FEM. Though simple, nonlinear MDOF systems are capable of reproducing the complicated nonlinear structural responses (Pampanin et al. 2003). OCM models the nonlinear behavior of structural members by concentrating inelastic deformations at the ends of elements, with inelastic springs with hysteretic properties. The fiber element method (Spacone et al. 1996a, b; Haselton et al. 2008) is a moderately complex method widely used for simulating nonlinear seismic response of medium rise concrete structures. It is best to include numerical tools for all these methods in an integrated simulator. Then a user has a high flexibility in choosing a suitable analysis method depending on the characteristics and importance of each structure and available computing resources.

Automated Analysis Model Generation

It is a challenging task to automate the analysis model construction for millions of buildings in a metropolis, based on GIS data. Although GIS is a prominent source of input data for an integrated earthquake simulator, the current GIS data does not contain the necessary data like structural skeleton and material properties; only the information like location, height, shape, etc. are included in the current GIS. The difficulties in making analysis model significantly increase with the complexity of the analysis method. As an example, analysis model construction for SDOF or MDOF is way easier than analysis model construction for OCM or fiber element method. OCM and fiber element methods require detailed information of the structural skeleton, which is difficult to be generated automatically from GIS data.

Even though the present GIS does not include the necessary data for structural response analysis, it is possible to generate an approximate analysis model based on the design procedures and recommendations provided in relevant design codes and handbooks. In the absence of necessary data in GIS or other sources, such approximate models, which comply with design manuals, are useful in obtaining a probable seismic disaster of a large metropolis. An approximate method of constructing MDOF models of residential buildings using the available GIS data, which is proposed by Hori (2011), is given below.

Approximate MDOF Model Generation Based on GIS Data

The governing equation of a building, which is subjected to seismic acceleration $\ddot{z}(t)$, modeled as an MDOF system is given by

$$\mathbf{M}\ddot{\mathbf{U}}(t) + \mathbf{C}\dot{\mathbf{U}}(t) + \mathbf{K}\mathbf{U}(t) = \ddot{\mathbf{z}}(t)\mathbf{M}\mathbf{1}, \quad (1)$$

where the vector $\mathbf{1} = [1, 1, \dots, 1]^T$. The data provided by the current GIS is insufficient to define the mass, damping, and stiffness matrices,

which are represented by $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$. However, if rewritten in the form used for modal analysis, the recommendations given in design manual can be utilized to solve the above problem. To that end, the natural frequencies and corresponding modes of the undamped system is found by solving the following eigenvalue problem:

$$(\mathbf{K} - \omega_n^2 \mathbf{M})\Phi_n = 0$$

The above eigenvalue problem can be easily obtained by setting $\mathbf{U} = \Phi \exp(i\omega t)$, $\mathbf{C} = 0$ and $\ddot{\mathbf{z}}(t) = 0$ in Eq. 1. Solving this eigenvalue problem, the n^{th} natural frequency, ω_n , and the corresponding mode shape, Φ_n , can be obtained; $n = 1, 2, \dots, N$, where N is the dimension of the matrices. The N mode shapes or eigenvectors form a basis; in the presence of any repeated frequencies, the associated modes should be orthogonalized. The unknown $\mathbf{U}$ can be expressed using these N basis functions as

$$\mathbf{U} = \sum q_n \Phi_n. \quad (2)$$

Substituting Eq. 2 to Eq. 1 and following the standard modal analysis procedures, the following N set of differential equations can be obtained (Datta 2010):

$$\ddot{q}_n(t) + 2\xi_n \omega_n \dot{q}_n(t) + \omega_n^2 q_n(t) = \ddot{z}_n(t), \quad (3)$$

where ξ_n is the damping ratio and $\ddot{z}_n(t)$ is the external inertial force corresponding to the n^{th} mode. The damping ratio and inertial force due to seismic loading are given by

$$\xi_n = \frac{\Phi_n^T \mathbf{C} \Phi_n}{2\Phi_n^T \mathbf{M} \Phi_n} \text{ and } \ddot{z}_n = \frac{\Phi_n^T \mathbf{M} \mathbf{1}}{2\Phi_n^T \mathbf{M} \Phi_n}.$$

According to the standard procedure of MDOF, the N equations given by Eq. 3 are solved for q_n 's with proper boundary conditions and the unknown $\mathbf{U}$ is found using Eq. 2. It is not necessary to use all the N modes, and the solution can be approximated with a selected set of modes.

Integrated Earthquake Simulation, Table 1 Period and damping ratio of the fundamental mode for different types of structures. H is the height of a building

Building type	$T_1/(s)$	ξ_1
Wooden house	0.2–0.7	0.02
Reinforced concrete	$0.02 H$	0.03
Steel reinforced concrete	$0.03 H$	0.02

Often, only the first few modes are used for short buildings. As an example, the first three modes are used for buildings with the period of fundamental mode shorter than 0.5 s (Hori 2011).

In the absence of necessary data to define M , C , and K of a particular building, approximate analysis model can be constructed based on the standard dynamic properties given in building design codes. As an example, the standard values of the period T_1 and the damping ratio ξ_1 of the fundamental mode residential buildings recommended by the Japanese design code are given in Table 1.

Further, the periods and damping ratios of second and third modes can be obtained from the following two empirical relations:

$$\begin{bmatrix} T_2 \\ T_3 \end{bmatrix} = \begin{bmatrix} 1 \\ \frac{3}{5} \\ 1 \\ \frac{5}{5} \end{bmatrix} T_1$$

$$\xi_{n+1} = \begin{cases} 1.4 \xi_n & \text{for reinforced buildings} \\ 1.3 \xi_n & \text{for steel reinforced buildings} \end{cases}$$

The above empirical relations make it possible to estimate the natural frequencies, $\omega_n = 2\pi/T_i$, and the damping ratios of the first three modes, which are sufficient for solving Eq. 3 for the amplitudes of the first three modes. Finally, the response can be estimated with Eq. 2. The required modal shapes can be easily estimated since the vibration modes of the dominant modes are known. The dominant modal shapes of buildings are given in standard textbooks, and even the modes of a cantilever beam are a good approximation (Hans and Boutin 2008).

Similar to the above given procedure, approximate analysis models for more complex analysis methods like OCM and fiber element model can be generated based on recommendations given in design manuals and handbooks. Unlike in the case of MDOF, automated model constructions for these methods are more challenging since these methods require structural skeleton details. The generation of structural skeletons from GIS data is straightforward when floor plan of a structure is made of multiple rectangles. However, if a building's shape changes with the floor number or has complex outer shape, the process of structural skeleton generation is complex and requires expertise in architecture and computational geometry. The spacing and the dimensions of the structural elements can be estimated based on the recommendations given in design manuals. As an example, 1/5 of floor height is often recommended as the height of beams. Obviously, automated FEM model construction is the most challenging.

Figure 5 shows the maximums of the inter-story drift angle compiled out of 400 simulations with different observed earthquake observations. The input strong ground motion for each building is computed using the 1D wave theory, using the details of underground structures and seismic waves recorded during 400 different earthquakes. The analysis models for buildings are automatically generated using the abovementioned approximate method for MDOF model generation from GIS data. Such Monte Carlo simulations can be used for more reliable earthquake disaster predictions.

Summary

In this chapter, the need of integrated earthquake simulation, a short overview of existing integrated earthquake simulators, and some remaining challenges are presented. The available integrated earthquake simulators have included only the earthquake hazard simulation

Integrated Earthquake Simulation, Fig. 5 Maximum inter-story drift angle obtained from 400 seismic response analysis simulations (Provided by Kohei Fujita, Department of Civil Engineering, University of Tokyo)

and earthquake disaster simulations. One of the remaining challenges in earthquake disaster simulation is automation of analysis model construction for complex analysis methods like fiber element model or FEM. Even though tsunami disasters are catastrophic, the present integrated systems have not included tsunami disaster simulations. It surely is challenging to develop numerical tools for tsunami disaster simulations including damages to structures. Even though tsunami disasters are rare, it is an essential item for an integrated system. The least developed is the simulations of human actions against earthquake disasters. The available numerical tools for evacuation simulations have to be further improved and enhanced with high-performance computing for simulating large domains. Out of all the numerical tools required for an integrated earthquake simulator, simulation of the recovery process is the least developed. It should be an invaluable tool for the decision makers, if a numerical method is developed to find the optimal way to allocate resources for recovering from a given earthquake disaster.

Earthquake geological effects; Environmental seismic intensity; Macroseismic scale

Introduction

Earthquake intensity scales were introduced at the end of the nineteenth century (e.g., Rossi-Forel, Cancani, Mercalli) in order to characterize source parameters, damage distribution, and environmental impact of relevant seismic events. These intensity scales were based on a classification of earthquake effects on humans, on buildings, and on the natural environment.

Intensity provides a measure of earthquake-induced damage both at a site (local intensity) and at the epicenter (epicentral intensity). It is important to note that intensity evaluations consider the coseismic effects in the whole range of frequencies of vibratory ground motion, together with those resulting from static, finite deformations (fault ground ruptures). It is common practice to use the term “macroseismicity” to describe effects that are measurable with the intensity scales, because very small earthquakes (“microseismicity”), commonly considered intensity degree one (I), are beyond the sensitivity level of these scales.

Most common intensity scales are divided in to twelve degrees using roman numbers (I to XII).

The diagnostic effects for low intensity degrees (I to V) are those on humans, then (VI to IX) those on buildings, and for the highest degrees (X to XII) those on the natural environment. In fact, the earthquake environmental effects (EEEs) start to be noticeable from intensity $\geq IV$ as indicated in the Environmental Seismic Intensity scale (ESI-07 scale; Michetti et al. 2007), which is the subject of this chapter.

In spite of the increasing development of the instrumental record of earthquakes from the second half of the twentieth century, macroseismic intensity analyses are still the usual practice when analyzing both historical and recent earthquakes. Recent earthquakes provide the opportunity to compare earthquake damage levels and instrumental records of horizontal ground acceleration to classify and properly quantify the recorded effects on buildings and environment and consequently to refine intensity scales.

By contrast, historical earthquakes only can be explored by macroseismic analyses, and intensity is the only parameter that allows an estimate of the earthquake size to be made. Experience gained from the macroseismic analyses of instrumental events led to the development of empirical relationships in order to approximately estimate the moment magnitude (M_w) of historical events from earthquake intensity distribution. As a result, instrumental records are in the best case available from the first half of the twentieth century; however, historical intensity analyses (extended in some regions back to the sixth to seventh century B.C.) are behind most of the seismic hazard analyses, seismic-building codes, and nuclear regulatory guides worldwide. Therefore, the use and refinement of intensity scales in earthquake analysis is still, and will continue to be, imperative to the society.

ESI-07 scale (Michetti et al. 2007) classifies earthquake environmental effects (EEEs) qualitatively as described in previous macroseismic intensity scales (e.g., MCS, MSK, MM). The ESI-07 scale has been developed primarily to properly describe and quantify EEEs for different intensity levels, based on the extensive amount of observations and research accumulated in the past decades in this field (e.g., Reicherter et al. 2009;

Audemard and Michetti 2011). Moreover, the ESI-07 scale has been introduced to fill the gaps of some modern macroseismic intensity scales, such as the European Macroseismic Scale (EMS-98; Grunthal 1998; Musson et al. 2010), which basically excludes EEEs from intensity assessment. Finally, the ESI-07 scale has also the objective of incorporating paleoseismic analysis into the macroseismic studies, extending the information on earthquake intensity data to a geologic time window in the order of some tens of kyrs.

The ESI-07 scale draws upon the expertise of a group of geologists, seismologists, and engineers under the support of the International Union for Quaternary Research (INQUA). The definition of the intensity degrees has been the result of a revision of the EEEs caused by a large number of earthquakes occurring in different parts of the world, conducted by the “INQUA International Focus Group on ► Paleoseismology and Active Tectonics” since the year 2003. The scale was formally approved during the XVII INQUA Congress, held in Cairns (Australia) on August 2007. The ensuing literature includes applications of the scale with a global coverage (e.g., Ali et al. 2009; Berzhinskii et al. 2010; Di Manna et al. (2013); Fountoulis and Mavroulis 2013; Gojsar 2012; Guerrieri et al. 2008; Lalinde and Sanchez 2007; Mavroulis et al. 2013; Ota et al. 2009; Papanikolaou 2011; Papathanassiou and Pavlides 2007; Serva et al. 2007; Tatevossian 2007). More recently, Silva et al. (2014) implemented the first official Catalogue on Earthquake Environmental Effects published by the Geological Survey of Spain (IGME) based on the On-line EEE Catalogue hosted at the Geological Survey of Italy (ISPRA) (<http://www.eeecatalog.sinanet.apat.it/terremoti/index.php>).

In the following sections, we will analyze the role of earthquake environmental effects in the existing macroseismic scales, how EEEs are classified (primary and secondary effects) and incorporated to the ESI-07 scale, the guidelines for the application of the scale, and finally the use of this intensity scale in paleoseismic research. The original text of the scale after Michetti et al. (2007) can be found in Appendix 1.

Earthquake Environmental Effects in the Macroseismic Scales

As mentioned in the introduction, intensity is a description of an earthquake based on the effect to humans, to buildings, and to the natural environment. Macroseismic scales classify these effects for each intensity level. A classification is not a measurement, and there is no way to define the “energetic distance” between different degrees of an intensity scale. In fact, macroseismic classifications are based on empirical qualitative scales, which by definition include significant subjectivity or, better, expert judgment. For this reason, all the scales use integer values from I to XII. Therefore, the only mathematical property that we can use is the order (and this is why the roman numerals are used for defining the intensity degrees).

The scientific worth of intensity scales, however, is to order the coseismic effects in degrees that try to include phenomena indicative of large differences in the strength of the earthquake at a site. Intensity IX in all scales of the “Mercalli family” (or, for the sake of precision, “Cancani family,” since Cancani was the first to introduce a 12° intensity scale) describes a scenario of effects, or a level of shaking, that is completely different from (much higher than) intensity VIII and completely different from (much lower than) intensity X. This is the “power of resolution” of the scales. Even with quite a “naive” description of the earthquake, intensity is of paramount importance in seismology and geology and engineering, primarily because intensity allows us to retrieve invaluable information from the historical record of seismicity. The evolution of the scales in the past century has been an effort to keep intensity in line with new knowledge in earthquake engineering and geology and to provide classifications of the effects with increasing objectivity and repeatability but within a substantial continuity with the original intensity scales developed by Rossi-Forel in 1883, Mercalli in 1889, and Mercalli-Cancani-Sieberg (MCS; Sieberg 1930).

All the intensity scales (Rossi-Forel, Mercalli, MCS, MSK, Mercalli Modified) consider the

earthquake environmental effects as diagnostic elements for intensity evaluation. This is especially relevant from intensity degrees $\geq$ IX, where intensity evaluation based on building damage nearly saturates (Michetti et al. 2007). However, some modern practices of macroseismic investigation (e.g., Grunthal 1998) tend to only focus on the effects on humans and the anthropic environment, overlooking the earthquake environmental effects, based on the opinion that these effects are too variable and aleatory. As aforementioned, this is especially the case for the new European Macroseismic Scales (EMS-98; Grunthal 1998; Musson et al. 2010) and its impact in European building codes.

Nevertheless, other authors (e.g., Dengler and McPherson 1993; Serva 1994; Serva et al. 2007; Dowrick 1996; Hancox et al. 2002; Michetti et al. 2004; McCalpin 2009) have provided clear evidence that the characteristics of geological and environmental effects are an essential piece of information in order to understand how intensity grows with the earthquake size (for seismic events with the same hypocentral depth). In this sense, intensity combines the effects of seismic shaking with local topographic and geological conditions (topographic and site-effect amplifications or attenuations) triggering temporal or permanent environmental effects in the landscape, which nowadays are widely retrievable from historical sources and/or paleoseismic research. Intensity is therefore a way to classify the interaction between the earthquake and the environment (people, objects, buildings, lifelines, trees, soils, slopes, rivers, aquifers, coastlines, etc.).

The record of earthquake environmental effects extends the set of information even far from urban zones, offering a better and more complete picture of the seismic scenario. Additionally, environmental effects are in many cases a direct source of damage in urban areas (e.g., liquefaction processes, large slope movements), sometimes even exceeding the damage produced by seismic shaking itself (e.g., tsunamis). This constitutes a keystone for intensity assessment in some damaged zones, as it is difficult to differentiate seismic-shaking damage from that

produced by environmental effects through the application of traditional intensity scales. Most of these traditional scales consider the occurrence of observable earthquake environmental effects from intensities $\geq VI$, noticeable from intensity VIII, and destructive or devastating for intensities $\geq IX$, but with descriptions somewhat qualitative and not properly classified.

The ESI-07 scale therefore provides a classification and quantification of earthquake environmental effects for the different intensity degrees, offering quantitative numerical data for the size of primary effects (surface faulting and coseismic uplift/subsidence) and secondary effects (slope movements, ground cracks, liquefaction processes, tsunamis). Other environmental effects, with poor to no potential of preservation in the geological or geomorphological records, such as hydrological anomalies in springs and wells, tree shacking, jumping stones, and dust clouds, are also included but providing qualitative descriptions. The scale also highlights the occurrence of frequent, characteristic, and diagnostic features on the assemblage of earthquake environmental effects for the different intensity degrees (see Appendix 1).

Consequently, ESI-07 scale allows an assessment of seismic intensity based only on the earthquake environmental effects. This can be regarded as an update, reclassification, and quantification of environmental effects included in the traditional macroseismic scales (MCS, MSK, MM). Its use, alone (in unpopulated regions) or, as a rule, integrated with the macroseismic traditional scales (for instance, intensity degree IX on the ESI-07 is equivalent to degree IX on the MCS, MM, and MSK scales; Michetti et al. 2004), will offer a more comprehensive picture of the earthquake's scenario and impact and a more consolidated estimate of intensity, allowing, therefore, a better comparability among different earthquakes.

Primary and Secondary Earthquake Environmental Effects in the ESI-07 scale

Earthquake environmental effects (EEEs) are all the phenomena generated in the natural

environment by a seismic event. These can be temporal or permanent, holding a different potential of preservation in the geological record. Typically, from intensities $\geq VIII$, EEEs can be permanently printed in the geology and landscape of a zone, being susceptible of paleoseismic analysis (Fig. 1). The ESI-07 scale classifies the EEEs in two main types: (a) primary and (b) secondary effects. While primary effects (e.g., surface faulting) are useful to directly assess the earthquake intensity, the nature, dimensions, and areal extent of secondary effects (mainly landslides and liquefaction processes) allow the complementary estimation of the epicentral intensity of an earthquake.

Primary Effects
